Haemolysis after etomidate: comparison of propylene glycol and lipid formulations

A. DOENICKE, M. F. ROIZEN, R. HOERNECKE, M. MAYER, P. OSTWALD AND J. FOSS

Summary

We sought to determine if the solvent in the formulation of etomidate is responsible for haemolysis in patients. In a randomized, prospective, double-blind study of 49 patients undergoing otolaryngological surgery, patients received etomidate dissolved in propylene glycol or in lipid emulsion. Concentrations of free haemoglobin and haptoglobin were measured before and for up to 360 min after injection of etomidate. Free haemoglobin concentrations increased by 216.8 mg litre^{-1} in patients who received the propylene glycol formulation and by 11.8 mg litre^{-1} in the lipid emulsion group ($P \leq 0.0004$). Correspondingly, reductions in haptoglobin concentrations were significantly greater in the propylene glycol group ($P \leq 0.002$). We conclude that with respect to haemolysis, lipid emulsion is superior to propylene glycol as a solvent for etomidate. (*Br. J. Anaesth.* 1997; **79**: 386–388).

Key words

Formulations, etomidate. Anaesthetics i.v., etomidate. Complications, haemolysis. Blood, haemolysis.

We first suspected that etomidate formulated in propylene glycol causes haemolysis after observing a reddish discolouration of the sera of volunteers treated with etomidate dissolved in propylene glycol.[1] We suspected that this reflected intravascular haemolysis caused by the high osmolality of etomidate (4965 mosmol litre^{-1}) dissolved in propylene glycol.[2]

In this study we attempted to confirm the hypothesis that etomidate dissolved in propylene glycol causes haemolysis and that this is not associated with a more physiological solvent (lipid emulsion). In lipid emulsion, etomidate has a near physiological osmolality of 400 mosmol litre^{-1}.

Methods and results

After obtaining Institutional Review Board approval and informed consent, we studied 49 patients undergoing otolaryngological surgery, randomly allocated to receive etomidate in propylene glycol or in a lipid emulsion preparation for induction of anaesthesia. On the evening before and 1 h before operation, each patient was premedicated with lormetazepam 2 mg orally. Patients were given fentanyl 2 μg kg^{-1} i.v. and atracurium 0.07 mg kg^{-1} i.v. for induction of anaesthesia, followed 3 min later by etomidate 0.3 mg kg^{-1} i.v. Patients in the propylene glycol group received Hypnomidate (Janssen, Neuss, Germany), etomidate 2 mg ml^{-1} of an aqueous solution of 35 vol% propylene glycol. Patients in the lipid emulsion group received Etomidate-Lipuro (B. Braun, Melsungen, Germany), etomidate 2 mg ml^{-1} of fat emulsion consisting of soy bean oil, medium-chain triglycerides, egg lecithin and glycerol. Neuromuscular block was produced with atracurium 0.5 mg kg^{-1} i.v. before tracheal intubation. During induction with etomidate, patients' lungs were ventilated with oxygen; subsequently, they were ventilated using a mask and 1–1.5% isoflurane in oxygen without nitrous oxide. After tracheal intubation, anaesthesia was maintained with 0.5–1.2% isoflurane and 65% nitrous oxide in oxygen. During operation, fentanyl i.v. was administered as needed. At the end of surgery, all patients were given droperidol 1.25–2.5 mg i.v. A second dose of etomidate was not given during anaesthesia. Patients also received an infusion of 1500 ml of a balanced electrolyte solution to reduce the dilution effect of blood sampling.

To record and quantify haemolysis, free haemoglobin concentrations in plasma before and 5 min after administration of etomidate were measured by an antigen–antibody nephelometer test. As an additional measure of haemolysis, haptoglobin concentrations in serum were measured by enzyme immunoassay before and 120, 240 and 360 min after administration of etomidate. At each measurement time, packed cell volume (PCV) was

Table 1 Comparison of serum free haemoglobin (mg litre^{-1}) and serum haptoglobin (g litre^{-1}) concentrations in the two groups. Serum haptoglobin concentrations are corrected for changes in packed cell volume. Values are (mean (SEM))

Time of measurement	Etomidate in propylene glycol ($n=24$)	*P* value compared with baseline	Etomidate in lipid emulsion ($n=25$)	*P* value compared with baseline	*P* value between groups
Free haemoglobin					
Baseline	42.2 (9.3)		42.3 (9.3)		0.996
5 min	259.0 (15.1)	0.0004	54.1 (5.7)	0.289	0.0004
Haptoglobin					
Baseline	1.78 (0.15)		1.79 (0 13)		0 950
120 min	1.10 (0.13)	0.0004	1.47 (0.13)	0.0004	0 042
240 min	0.85 (0 11)	0.0004	1.36 (0.12)	0.0004	0.003
360 min	0.84 (0.11)	0.0004	1.39 (0.13)	0.0004	0.002

also measured, and correction in haptoglobin concentrations was made for the dilution effect. The *t* test for non-paired samples and covariance analysis was used for statistical analysis with $P \leq 0.05$ considered statistically significant.

The two groups did not differ in age, height, weight, sex distribution, duration of procedure or dose of etomidate received. PCV values did not differ between groups. Mean free haemoglobin concentrations after etomidate in propylene glycol increased significantly from 42.2 (SEM 9.3) mg litre^{-1} at baseline to 259 (15.1) mg litre^{-1} 5 min later ($P \leq 0.0004$) and in the lipid emulsion group from 42.3 (9.3) to 54.1 (5.7) mg litre^{-1} ($P=0.289$) (table 1). Between-group differences were significant 5 min after administration of etomidate ($P \leq 0.0004$).

Serum haptoglobin concentrations decreased significantly compared with baseline in both groups after administration of etomidate. The reduction in free haptoglobin after etomidate in propylene glycol was significantly greater after 240 and 360 min ($P \leq 0.003$ and $P \leq 0.002$, respectively) (table 1).

Comment

Several adverse effects caused by propylene glycol have been described: hypotension, pain on injection, lactic acidosis and pulmonary hypertension.[1 3–5] In our study, a single injection of etomidate 0.3 mg kg^{-1} dissolved in propylene glycol increased free haemoglobin (514%) and decreased serum haptoglobin (52.8%) concentrations significantly, indicating intravascular haemolysis. Free haemoglobin is bound within a few minutes by haptoglobin, forming a haptoglobin–haemoglobin complex. The half-life of haptoglobin is 3–4 days compared with that of the haptoglobin–haemoglobin complex of only 8 min. If intravascular free haemoglobin increases, haptoglobin concentration decreases, which is a measurable sign of haemolysis.

Haemolysis and cell lysis associated with an induction dose of etomidate dissolved in propylene glycol may not cause detectable renal injury in healthy individuals. However, several other drugs are also dissolved in propylene glycol such as lorazepam (osmolality 12800 mosmol litre^{-1}) and nitroglycerin (osmolality 4550 mosmol litre^{-1}).[2] Combined use of drugs dissolved in propylene glycol may increase the likelihood and severity of haemolysis. If etomidate dissolved in propylene glycol or other drugs with similar formulations are injected repeatedly after short intervals, or if they are used in combination, circulating haptoglobin may be depleted completely. Under such circumstances free haemoglobin from haemolysis may exceed binding capacity and exert toxic effects.[6]

Intraoperative autotransfusion in patients who have received etomidate dissolved in propylene glycol also makes haemolysis problematic. It has been shown that infusion of packed red cells, especially from autotransfusion, decreases haptoglobin concentrations.[7] In fact, haptoglobin was undetectable in seven of 47 patients after autotransfusion. Etomidate is a desirable induction agent for older, less healthy patients because it does not effect cardiovascular stability. These patients often undergo procedures (total hip replacement or vascular surgery) that use autotransfusion. In such patients, the combined effects of etomidate in propylene glycol and autotransfusion may decrease haptoglobin concentrations. We speculate that those likely to be affected include patients with other risk factors, such as impaired renal function or patients in shock who need high re-transfusion volumes.

Our results are consistent with the hypothesis that propylene glycol is a less safe vehicle than lipid emulsion for etomidate. Side effects associated with propylene glycol may be toxic for some patients.

Enhanced choline acetyltransferase activity does not explain the action of inhaled convulsants

R. GRIFFITHS, P. IONESCU, Z. FANG, D. D. KOBLIN AND E. I. EGER

Summary

Enhancement of choline acetyltransferase (ChAT) activity and increased intraneuronal acetylcholine (ACh) may explain the convulsant activity of some inhaled compounds. Enflurane, for example, enhances such activity. Accordingly, we measured choline acetyltransferase (ChAT) activity in rat cortical synaptosomes in the presence of two inhaled convulsants, flurothyl ($CF_3CH_2OCH_2CF_3$) and 1,2-dichlorohexafluorocyclobutane at partial pressures below and greatly exceeding those which produce convulsions *in vivo*. Neither agent changed the kinetic parameters, maximum velocity (*v*max) or Michaelis constant (K_m). The *v*max for controls in the flurothyl series was 016 (0.06) nmol mg^{-1} min^{-1} and the K_m was 0.23 (0.11) mmol $litre^{-1}$. For the 1,2-dichlorohexafluorocyclobutane series of experiments the results for the controls were *v*max 0.23 (0.10) nmol mg^{-1} min^{-1} and K_m 0.20 (0.08) mmol $litre^{-1}$. Modification of ChAT activity did not contribute to the excitatory effects of these agents. (*Br. J. Anaesth.* 1997; **79**: 389-391).

Key words
Anaesthetics volatile. Enzymes, choline acetyltransferase. Nerve, neurotransmitters. Complications, convulsions.

Acetylcholine (ACh) is an excitatory neurotransmitter important for arousal and maintenance of consciousness.[1] The central cholinergic system may also play a role in the genesis of seizure.[2]

Enflurane enhances the activity of the enzyme responsible for ACh synthesis, choline acetyltransferase (ChAT).[3] To determine if this effect applies broadly, we investigated the effects of two volatile compounds with known convulsant properties, flurothyl and 1,2-dichorohexafluorocyclobutane, on the kinetics of ChAT in rat cortical synaptosomes.

Methods and results

With approval from the University of California San Francisco Committee on Animal Research, we studied 52 male (300–430 g), specific pathogen-free Sprague Dawley rats from Charles River Laboratories. Four rats were placed in individual plastic cylinders and the tail end of each cylinder had a rubber stopper with multiple holes. The tail and a rectal temperature probe passed through two of these holes, and the tail was secured with tape to a plastic extension of each cylinder.

Each cylinder was inserted into a slightly larger individual plastic chamber. A catheter for sampling inspired gas in the chamber and another tube for delivery of gases traversed the stopper at the "head" end of the chamber. Oxygen was flushed through the tube before beginning the study. The tubes at the tail ends were connected to a carbon dioxide adsorbent canister containing 200 g of fresh soda lime. To complete the system, the adsorbent canister was connected to a circulating fan that led to the head-end tubes. To permit delivery of compounds, we added a "T" connector between the carbon dioxide adsorber and the tail end of the four chambers. Finally, the system was connected with a demand oxygen supply (bypass flow approximately 50 ml min^{-1}) for delivery of oxygen after closure of the system.

We initially flushed the system until the oxygen concentration was 95% or higher. Oxygen concentration was measured with a Pauling (polarographic) meter (Beckman model E2). After closing the system (oxygen supplied on demand), flurothyl (>99% purity, PCR Inc., Gainesville, FL, USA) or 1,2-dichlorohexafluorocyclobutane (>97% purity, PCR Inc., Gainesville, FL, USA) was introduced in sequentially increasing concentrations as liquid aliquots followed by a flush of oxygen. For each concentration, a 20-min equilibration period was allowed, during which we observed the rats for convulsion. If no convulsion occurred, we increased the concentration by 15–25%. The ED_{50} for convulsion was defined as the mean of the partial pressures in the chamber immediately below and just causing a convulsion.

Table 1 Effect of flurothyl and 1,2-dichlorohexafluorocyclobutane on choline acetyltransferase (ChAT) kinetic parameters, maximal velocity (*v*max) and Michaelis constant (K_m) (mean (SD)). Actual flurothyl concentrations measured at the end of the experiments were, mean 0.11 (SD 0.0035), 0.21 (0.0064), 0.43 (0.017), n=20. Actual 1,2-dichlorohexafluorocyclobutane concentrations measured at the end of the experiments were 2.11 (0.15), 4.13 (0.28), 8.86 (0.52), n=20

	Flurothyl (target concentrations)			
Kinetic parameter	Air	0.125 %atm	0.25 %atm	0.5 %atm
*v*max (nmol mg^{-1} min^{-1})	0.16 (0.06)	0.16 (0.06)	0.14 (0.01)	0.14 (0.03)
K_m (mmol litre^{-1})	0.23 (0.11)	0.22 (0.09)	0.21 (0.08)	0.21 (0.10)
	1,2-dichlorohexafluorocyclobutane (target concentrations)			
Air	2.5 %atm	5.0 %atm	10 %atm	
*v*max (nmol mg^{-1} min^{-1})	0.23 (0.10)	0.25 (0.10)	0.25 (0.10)	0.20 (0.06)
K_m (mmol litre^{-1})	0.20 (0.08)	0.19 (0.04)	0.20 (0.05)	0.17 (0.03)

The convulsive ED_{50} values for flurothyl and 1,2-dichlorohexafluorocyclobutane, respectively, were mean 0.156 (SD 0.004) %atm, n=24 and 5.54 (0.01) %atm, n=28.

With approval from the UCSF Committee on Animal Research, we prepared synaptosomes from the cortex of male Fisher rats (200–250 g) using the method described by Dunkley and colleagues.[4]

ChAT activity was determined using the method of Fonnum.[5] Synaptosomes were suspended (0.5 ml) in a medium containing NaCl 300 mmol litre^{-1}, ethylenediaminetetra-acetic acid (EDTA) 20 mmol litre^{-1}, neostigmine 1 mmol litre^{-1}, 0.5% (w/v) Triton X-100 and sodium phosphate 50 mmol litre^{-1} (pH 7.4), to a protein concentration of 0.5 mg ml^{-1}. The mixture was placed in a 10-ml gas-tight syringe containing either air or air and one of the test gases, and incubated in a water bath at 37°C for 10 min. Constant shaking allowed equilibration of the test gas with the synaptosome suspension. A substrate mixture (0.5 ml) containing choline bromide at concentrations of 0.05–2.00 mmol litre^{-1}, acetyl coenzyme A 2 mmol litre^{-1} and [^{3}H]acetyl coenzyme A 0.5° μCi in the incubation medium but without Triton X-100 was added to the synaptosome suspension, shaken gently and returned to the water bath for 30 min. Immediately after addition of the substrate mixture a 100-μl aliquot was withdrawn and ACh extracted using Kalignost (Koch-Light Lab Ltd, Bucks, UK).[5] These samples were used as time zero controls for background subtraction of radioactivity from the test samples. After 30 min, 100-μl samples were obtained in duplicate and ACh content measured by scintillation counting after Kalignost extraction.[5]

The concentration of test gas in the syringes at the end of the incubation was measured by gas chromatography. The synaptosome preparations were exposed to air with flurothyl at 0.125, 0.25 and 0.5%atm. The concentrations of 1,2-dichlorohexafluorocyclobutane in air were 2.5, 5.0 and 10.0%atm. Controls, exposed to air only, were included in each set of experiments.

Michaelis–Menten kinetic parameters, maximum reaction velocity (*v*max) and Michaelis constant (K_m) were calculated for ChAT in each experiment using rectangular hyperbola curve fit in SigmaPlot for Windows. Results were compared using Student's paired t test. $P<0.05$ was considered statistically significant.

Neither compound altered the kinetics of ChAT at any concentration tested (table 1).

Comment

Our previous work demonstrated that anaesthetizing concentrations of enflurane decreased the K_m of ChAT for choline bromide.[3] These findings led to our hypothesis that the convulsant effect of inhaled convulsants might result from enhancement of ChAT activity. The cholinergic system has been implicated in the genesis of seizures.[2] These findings are consistent with our hypothesis.

In conflict with our hypothesis, our results demonstrated that flurothyl and 1,2-dichlorohexafluorocyclobutane did not alter the kinetics of ChAT from rat cortical synaptosomes. There is a remote possibility that the lack of effect seen with the synaptosome preparation resulted from the different strain of rat used for the ChAT part of the experiment. Test concentrations of both agents were distributed either side of the convulsive ED_{50} for these agents *in vivo* in rats. It remains possible that ChAT kinetics were affected in amounts too small to be measured. However, in previous studies with enflurane,[3] a 35% decrease in the K_m of ChAT was detected, and a greater decrease would be expected in our experiments if ChAT kinetics were important.

Many other transmitter systems are also involved in the genesis of seizures and it may be that discrete mechanisms explain the epileptic capacity of each convulsant. At the crab neuromuscular junction, flurothyl selectively blocks inhibitory transmission (GABA) more than excitatory transmission (glutamate).[6]

Although the synaptosome preparation contains the machinery needed for neurotransmitter studies, the preparation has limitations which may influence the interpretation of this study. The preparation produces synaptosomes from nerve endings secreting diverse transmitters, not just ACh. Thus there is still the possibility of non-physiological crosstalk that could obscure drug effects. To summarize, the heterogeneous nature of the synaptosome preparation, together with the potential presence of more than one transmitter in cholinergic neurones, limits the interpretation of results from our system.

Although we found that modulation of ChAT activity does not contribute to the excitatory effects of volatile convulsants, this does not exclude ACh metabolism as a cause of the effects of such compounds and future studies may focus on other aspects of cholinergic function.

CASE REPORTS

Sevoflurane for difficult tracheal intubation

S. M. MOSTAFA AND A. M. J. ATHERTON

Summary

Three patients in whom difficult tracheal intubation was expected but awake fibreoptic intubation was not feasible presented for head and neck surgery. Anaesthesia was induced rapidly and smoothly by inhalation of sevoflurane followed by fibreoptic or conventional tracheal intubation. (*Br. J. Anaesth.* 1997; **79**: 392–393).

Key words

Anaesthetics volatile, sevoflurane. Intubation tracheal, difficult.

Sevoflurane is becoming regarded as the agent of choice for inhalation induction of anaesthesia. Several studies have demonstrated that rapid and smooth induction is possible with sevoflurane.[1–6] However, inhalation induction with this agent has not been reported in the management of a difficult airway. We report three patients in whom we chose to induce anaesthesia by inhalation of sevoflurane because difficulty in managing the airway was anticipated and other techniques were not suitable.

Case reports

Patient No. 1

A 68-yr-old man with a carcinoma of the left maxillary sinus presented for radical maxillectomy, cervical lymph node dissection and reconstructive surgery. He was hypertensive and had chronic lung disease. He had restricted mouth opening. Nasal intubation was not possible because both nostrils were occluded by the tumour. Awake fibreoptic intubation under local anaesthesia was likely to be impossible because of intraoral protrusion of the tumour, excessive secretions and blood in the oropharynx. The patient refused tracheotomy under local anaesthesia.

After premedication with temazepam 10 mg orally and glycopyrronium 200 μg, a 16-gauge i.v. cannula was inserted and a crystalloid infusion was commenced. Droperidol 2.5 mg and fentanyl 50 μg were given i.v. Standard monitoring included pulse oximetry and ECG. Oxygen was given for 5 min via a circle system with a close fitting mask followed by up to 4% sevoflurane and 66% nitrous oxide in oxygen. After 120 s anaesthesia was sufficiently deep to allow tracheal intubation with a cuffed 7.0-mm tube passed over a flexible fibreoptic laryngoscope (LF2, Keymed plc, UK). Thereafter, anaesthesia was maintained with isoflurane and nitrous oxide in oxygen, with increments of atracurium and fentanyl. Both surgery and anaesthesia were uneventful.

Patient No. 2

A 45-yr-old man presented for parathyroidectomy. Conventional intubation had been impossible during a previous anaesthetic. He was educationally subnormal, obese and had poor neck extension, coarse features with a large tongue, and very restricted mouth opening with only a few remaining teeth which were in poor condition. It was decided that conventional oral intubation would fail. He was unlikely to co-operate with awake intubation or tracheotomy. Therefore, it was decided to perform nasotracheal fibreoptic intubation.

He was premedicated with temazepam 10 mg orally and glycopyrronium 200 μg. He was given 100% oxygen for 5 min. Nitrous oxide 50% in oxygen was introduced with increasing concentrations of sevoflurane up to 7%. Initially maintaining a clear airway during anaesthesia proved to be difficult. Oxygen 100% was given until lightening of anaesthesia led to improvement in airway patency. Anaesthesia was administered successfully via the left nostril using a nasopharyngeal airway attached to a 15-mm tracheal tube connector and catheter mount connected to the anaesthetic system. Sevoflurane was reintroduced. A sufficient depth of anaesthesia was achieved and successful nasotracheal intubation was accomplished via the right nostril using a flexible fibreoptic laryngoscope. Anaesthesia for surgery was maintained as in the previous patient. The tracheal tube was removed at the end of surgery with the patient awake.

Patient No. 3

A 32-yr-old ASA III woman underwent uneventful resection of a left maxillary neuroblastoma with radical maxillectomy, orbital exenteration and resection of the nasal septum. She presented 5 days after this procedure for change of the obturator and packing.

S. M. MOSTAFA, FRCA, A. M. J. ATHERTON*, FRCA, Department of Anaesthesia, Royal Liverpool University Hospital, Prescot St, Liverpool L7 8XP. Accepted for publication: April 22, 1997.

*Present address: Department of Anaesthesia, Cardiothoracic Centre, Thomas Drive, Liverpool, L14 3PE.

Her inter-incisor distance was only 2 cm at full mouth opening because of masseter spasm. There was no nasal airway as the septum had been removed and the cavity packed. Local anaesthesia for the oropharynx and larynx was inappropriate and unlikely in view of the previous surgery.

As surgery did not involve the temporomandibular joint, mouth opening was likely to improve allowing easy maintenance of the airway after induction of anaesthesia. It was decided that inhalation induction would be appropriate, followed by conventional or fibreoptic laryngoscopy.

She was given midazolam 3 mg and glycopyrronium 200 μg i.v. on arrival in the anaesthetic room. Her lungs were preoxygenated for 5 min. Anaesthesia was induced with up to 4% sevoflurane in oxygen. Her jaw relaxed and it was possible to introduce a McCoy laryngoscope blade and to view the arytenoid cartilages with flexion of the laryngoscope tip. Therefore, suxamethonium 100 mg was given and the trachea was intubated with the aid of a gum elastic bougie. Thereafter anaesthesia and surgery were uneventful.

Discussion

Inhalation induction of anaesthesia is a well recognized technique in the management of the difficult airway. Its inherent safety depends on gradual and smooth deepening of anaesthesia. If loss of muscle tone leads to loss of airway patency then anaesthesia inevitably lightens with return of muscle tone. We believe that sevoflurane offers major advantages compared with the usual agent, halothane. Many of our patients have had recent anaesthesia for endoscopy or biopsy and repeated halothane anaesthesia should be avoided where possible. Induction is smoother, faster and more pleasant than with halothane or isoflurane,[1–6] with less coughing and breath-holding. If airway patency is lost, the lower blood solubility of sevoflurane leads to faster awakening. Although we used nitrous oxide in two of our patients, as we would have previously when using halothane, use of 100% oxygen as a carrier gas delays desaturation if obstruction occurs. Use of halothane without nitrous oxide sacrifices the benefit of the second gas effect resulting in a slower induction, whereas induction with sevoflurane in oxygen remains highly satisfactory, as in patient No. 3. Sevoflurane therefore offers a greater margin of safety than halothane in the management of the patient with a difficult airway.

Induction of anaesthesia in two of our three patients was smooth and fast. The third patient briefly developed airway obstruction but this was overcome readily without hypoxia. At no time during induction did Sp_{O_2} decrease to less than 96% in any of our patients. Oxygenation and ventilation, as confirmed by pulse oximetry and capnography, were satisfactory throughout induction in two of the three patients. The second patient briefly developed airway obstruction during induction. This was caused partially by loss of the airway before adequate depth of anaesthesia for intubation was achieved. This resulted mainly from the patient's abnormal anatomy. The obstruction was overcome by insertion of a nasopharyngeal airway before significant desaturation had occurred. Intubation was easy and rapid. The use of a laryngeal mask in these patients was not possible because of limited mouth opening and the type of surgery to be undertaken.

Concerns regarding sevoflurane cost and degradation by soda lime do not apply if it is used purely for induction. We have since used sevoflurane for inhalation induction in similar patients with success. We conclude that sevoflurane appears to be a useful agent for inhalation induction in patients with difficult airways and merits further investigation.

Transient radicular irritation after spinal anaesthesia with 2% isobaric lignocaine

D. RAMASAMY AND R. EADIE

Summary

A typical case of transient radicular irritation after spinal anaesthesia with 2% isobaric lignocaine is described. The definition and history of this syndrome and the implications of the use of pencil point needles with lignocaine for spinal anaesthesia are discussed. (*Br. J. Anaesth.* 1997; **79**: 394–395).

Key words

Anaesthetic techniques, subarachnoid. Anaesthetics local, lignocaine. Complications, transient radicular irritation.

In the past 5 yr, 5% hyperbaric lignocaine has been implicated increasingly in the cause of neurotoxicity after spinal anaesthesia. Its association with the cauda equina syndrome in continuous spinal anaesthesia with microcatheter techniques has been documented previously.[1] Sacral accumulation of the local anaesthetic (caused partly by the low flow rates of the hyperbaric solution through the microcatheter) together with its neurotoxicity were thought to be responsible.

It became apparent that the use of 5% lignocaine with pencil point spinal needles may also cause transient neurological deficits.[2 3] The term "transient radicular irritation" (TRI) has been used to describe such deficits. Pinczower and colleagues[4] noted some features common to this syndrome involving the use of 5% hyperbaric lignocaine. These were mainly: (1) bilateral radicular-like leg pain with or without back pain; (2) moderate or severe pain; (3) onset of pain within 24 h of surgery; (4) duration of pain greater than 24 h; and (5) no previous history of severe back or leg pain.

More recently 2% hyperbaric,[5] and now 2% isobaric solutions of lignocaine have also been implicated in TRI.[6 7]

We report a case of TRI which occurred when 2% plain isobaric lignocaine was injected through a 27-gauge Whitacre needle, when the aperture of the needle was directed caudally.

Case report

A 62-yr-old man presented for cystoscopy having been admitted in urinary retention. He had undergone cystoscopy, bladder neck incision and a transurethral resection of his prostate (TURP) 1 month previously, having had a 12-month history of hesitancy and frequency. This had been performed under an uneventful spinal anaesthetic using 0.5% heavy bupivacaine 2 ml via a 27-gauge Whitacre needle.

His past history included coronary artery bypass grafts in 1982, hypertension and congestive heart failure. He still had symptoms of angina with moderate exercise. He had no history of diabetes or chronic back pain. His medications included nifedipine, enalapril, frusemide, amiloride and aspirin. Routine preoperative tests, including a clotting profile, were within normal limits.

On this occasion, atraumatic dural puncture was performed in the sitting position at the first attempt at the L3–4 interspace, using a 27-gauge Whitacre needle. The side port of the spinal needle was directed caudally and injection of 2% plain isobaric lignocaine 3 ml was given over 4–5 s. No discomfort was elicited during insertion of the spinal needle or during injection of the local anaesthetic.

Cystoscopy, carried out in the lithotomy position, was uneventful and of short duration. Necrotic tags in the previous resection cavity were excised and adhesions to the verumontanum were divided. The patient remained haemodynamically stable during the procedure.

Twelve hours after operation, in the ward, he developed bilateral "burning" pain radiating from his buttocks to mid calves. This was uncomfortable enough for him to request oral analgesia (paracetamol–codeine) from which he gained partial relief. In particular he gave no history of motor symptoms and was able to walk freely. He had no headache, tinnitus or diplopia.

On examination he was afebrile and had no evidence of sensory loss or motor weakness, although he had diminished ankle jerks in comparison with his knee jerks. There was no record of his lower limb reflexes on admission. Sphincter tone was normal.

It was decided after consultation to treat him conservatively and his symptoms settled over the next 5 days. His urinary catheter was removed 2 days after operation and he voided successfully. He was

discharged 5 days after operation. He was reviewed 4 months later with no recurrence of sensory symptoms. In particular, his ankle jerks, although present, were still diminished.

Discussion

The potential neurotoxicity of 5% hyperbaric lignocaine has been investigated *in vitro* by Lambert, Lambert and Strichartz[8] using desheathed bullfrog sciatic nerves. These nerves bear some resemblance to the similarly unprotected cauda equine in mammals. They found that exposing the nerve fibres to 5% lignocaine with or without 7.5% glucose for 15 min produced irreversible conduction block. Indeed there was no recovery of the compound action potential (CAP) in nerve fibres exposed to 5% lignocaine in 7.5% glucose for 3 min or longer. Furthermore, exposure to 1.5% lignocaine for 15 min produced partially reversible conduction block.

Bainton and Strichartz[9] studied the effect of 15 min exposure of (≈1%) lignocaine 40 mmol litre^{-1} on the CAP of frog sciatic nerves. After a washout period of 2 h with Ringer's solution, the CAP remained degraded. This could not be explained simply on the basis of concentrations of residual lignocaine present after washout. It appears therefore that some local anaesthetics, if present in sufficiently high concentrations, may be potentially neurotoxic. Beardsley and colleagues[10] investigated maldistribution of hyperbaric solutions of dye in spinal models using Whitacre and Quincke spinal needles. They suggested that the type and gauge of the spinal needle, speed of injection and direction of the needle may contribute to maldistribution of the local anaesthetic in the spinal canal. Interestingly they suggested that exposure to peak concentrations of more than 2% lignocaine may be the clinical threshold for toxicity. They had deduced this from peak sacral dye concentrations found after injections which were directed sacrally through 25- and 27-gauge Whitacre needles.

In clinical practice, Tarkkila, Huhtala and Tuominen[11] studied 600 patients who underwent spinal anaesthesia. They found that 10% of patients anaesthetized with 5% lignocaine had transient neurological symptoms similar to those described by our patient. They concluded that the use of 5% hyperbaric lignocaine for spinal anaesthesia should be reconsidered. Hampl and colleagues[12] studied 276 patients undergoing elective gynaecological and obstetric surgery under spinal anaesthesia with either 5% hyperbaric lignocaine or hyperbaric bupivacaine. They found a 37% incidence of pain and dysaesthesia in those who received hyperbaric lignocaine. This was typically bilateral, involved the thighs and back, and persisted for less than 3 days.

We suggest that our patient's symptoms may have been caused by a neurotoxic concentration of lignocaine at the sacral nerve roots. Unlike the hyperbaric solution where a low flow rate contributes to maldistribution, the high speed of injection with the isobaric solution and the sacral direction of the Whitacre needle probably contributed to the caudal deposition of the local anaesthetic.

It is unlikely that trauma played a causative role as there was no discomfort elicited on placing the spinal needle and the symptoms were bilateral.

As the patient remained haemodynamically stable, ischaemia was also unlikely. Chronic lumbar disc pathology was also probably unlikely as he had no history of chronic back pain. Furthermore, 2% lignocaine has been reported previously to cause a cauda equine syndrome,[13] although this involved accidental intrathecal injection of 2% lignocaine 32 ml intended for extradural anaesthesia.

Pinczower and colleagues,[4] in a study of 17 cases, implicated 2% isobaric lignocaine in the cause of neurotoxicity, although no patient had symptoms typical of their definition of TRI. More recently, Hampl and colleagues[5] found that the incidence of TRI was similar with 2% hyperbaric lignocaine and 5% hyperbaric solutions. Furthermore, Pollock and colleagues,[6 7] implicated 2% isobaric and 5% hyperbaric solutions of lignocaine in causing similar rates of TRI.

In summary, we believe that the use of 5% hyperbaric lignocaine and 2% isobaric lignocaine for spinal anaesthesia should be re-evaluated and that the possible maldistribution of local anaesthetics intrathecally and their consequences should be considered when directing pencil point needles caudally.

Unsuspected difficult intubation caused by a laryngeal web

Z.-K. CHONG, B. JAWAN, Y.-Y. POON AND J.-H. LEE

Summary

We report a case of unsuspected difficult intubation in an adult caused by laryngeal web formation in the anterior commissure of the larynx. After induction of anaesthesia, most parts of the posterior commissure of the vocal cords were seen clearly at laryngoscopy, but a 7.5-mm internal diameter (id) tracheal tube could not be advanced below the level of the vocal cords because of resistance. Intubation was re-attempted several times after oxygenation by mask with trials of smaller tubes. Finally, a 5.0-mm id cuffed tube was passed successfully through the vocal cords, and secured in place. Because of the unexpected difficulties in intubation, an otolaryngologist was consulted to examine the larynx with a microscope. A web of 0.5 cm in the anterior commissures was found which caused subglottic stenosis. (*Br. J. Anaesth.* 1997; **79**: 396–397).

Key words
Larynx, dammage. Larynx, laryngoscopy. Complications, stenosis. Intubation tracheal, difficult.

We present a rare case of difficult intubation in an adult after induction of anaesthesia caused by a laryngeal web.

Case report

A 65-yr-old male, ASA II, was admitted for radical nephroureterectomy because of malignant obstructive uropathy. Past surgical history included laparotomy under general anaesthesia more than 30 yr previously and extracorporeal shock wave lithotomy (ESWL) twice under i.v. general anaesthesia without tracheal intubation in the past month. Medical history revealed that pulmonary tuberculosis had been diagnosed and treated decades ago. Mild hoarseness without dyspnoea was noted. Laboratory data, including electrocardiogram, haematology and serum electrolytes, were normal. Chest x-ray revealed minimal fibrotic pulmonary tuberculosis in the right upper lung. General anaesthesia was induced with fentanyl 100 μg and 2.5% thiopentone 300 mg i.v. No premedication was given.

Suxamethonium 60 mg was given to facilitate tracheal intubation. Most parts of the posterior commissure of the vocal cords were seen clearly at laryngoscopy, but a 7.5-mm internal diameter (id) tracheal tube could not be advanced below the level of the vocal cords because of resistance. Intubation was re-attempted several times after oxygenation by mask with trials of smaller tubes. Finally, a 5.0-mm id cuffed tube was passed successfully through the vocal cords and secured in place. Because of the unexpected difficulties during intubation, an otolaryngologist was consulted to examine the larynx with a microscope. A web of 0.5 cm in the anterior commissures was found (fig. 1) which caused subglottic stenosis. The arytenoids, vocal cords and epiglottis were free of disease or tumour. The consultant advised no treatment because the web caused only mild hoarseness without any other symptoms. Bronchial culture was obtained. The operation was carried out as scheduled and the patient's trachea was extubated uneventfully in the post-anaesthesia recovery room. There was no respiratory problem noted during hospitalization. The patient was discharged from hospital 1 week later.

Discussion

The cause of difficult intubation in our case was extremely rare. There are only a few reports of difficult intubation caused by laryngeal web in the literature.[1–3] All were not suspected before induction of anaesthesia and most resulted in morbidity. Emergency tracheostomy was necessary before operation to maintain airway patency in one adult,[1] and after operation in two children because of airway obstruction after extubation.[2, 3] Severe respiratory distress was also noted in a child. Laryngeal webs consist of thin transparent or thick fibrous membranes and may be congenital or acquired. Congenital webs, usually symptomatic in infancy or early childhood, are the result of incomplete recanalization of the primitive laryngeal airway.[4] Their incidence has been estimated at approximately 1 in 10 000 births. Seventy-five percent of laryngeal webs are located at the level of the vocal cords, the remainder being either sub- or supraglottic. The

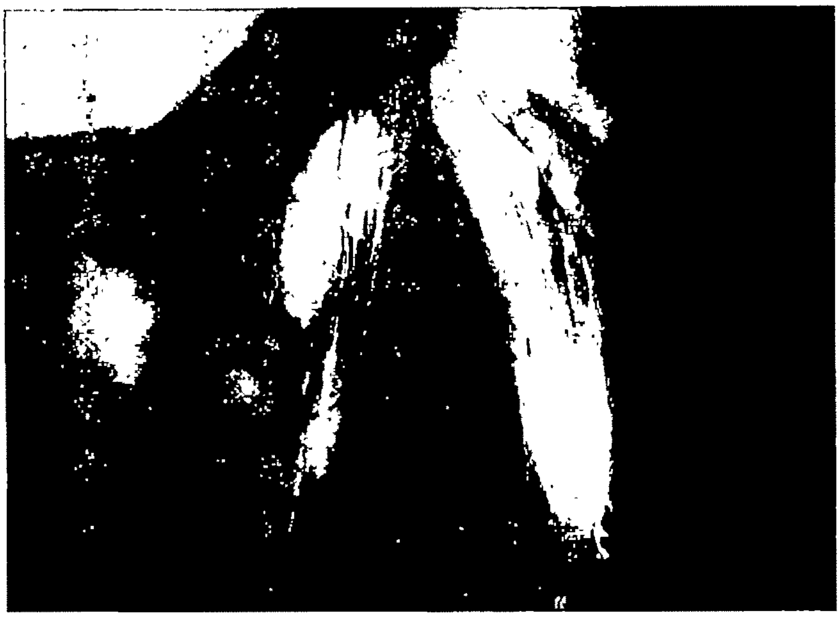

Figure 1 A laryngeal web of approximately 0.5 cm in the anterior commisure of the larynx, which caused subglottic stenosis, was seen clearly under a microscope

majority of glottic webs lie anteriorly between the cords; only 1–2% are located posteriorly.[5] The disease is suggested by clinical symptoms such as stridor, weak crying and feeding problems, but endoscopic vision is essential for a definite diagnosis.[6] Usually the symptomatic laryngeal web is treated by one of the following surgical procedures: surgical division, endoscopic insertion of a keel or laser treatment.[6 7] Webs without any clinical symptoms are not treated as the incised and divided adjacent cords may adhere together because of scarring.

The aetiology of laryngeal web formation in our patient is not known. Congenital anomaly, post-inflammatory or post-traumatic injuries may be possible causes. Our patient underwent laparotomy more than 30 yr ago without apparent complications. He also had pulmonary tuberculosis diagnosed and treated decades ago. Both of these may be possible causes of laryngeal web formation in this patient. Sputum culture for tuberculosis was negative.

Airway management of unsuspected laryngeal web is clinically the same as managing patients with subglottic stenosis. Different sizes of tracheal tube should be available during induction of anaesthesia and the tracheal tube should not be advanced with force when resistance is encountered. Further traumatic injuries to the cords should be avoided as it may induce scarring and enhance web formation in the future, especially if both sides of the cords are injured. Web formation in the posterior commissures has been reported after intubation[8]: if this is encountered, it is best to awake the patient, postpone the operation and consult an otolaryngologist for evaluation of the airway anatomy. For emergency surgery, examination of the larynx with a flexible fibreoptic laryngoscope under local and topical anaesthesia before re-attempting intubation may minimize traumatic injuries to the vocal cords. Increased risk of laryngospasm, trauma and distressing iatrogenic airway obstruction while participating in awake fibreoptic laryngoscopy should always be borne in mind. Anaesthesia via a laryngeal mask, which is not traumatic to the vocal cords, would be an alternative choice. Another important point is postoperative follow-up of the patient as local bleeding, oedema and further formation of web may occur. The patient should be warned of these complications and the condition should be mentioned to the surgeon and anaesthetist if surgery is contemplated in the future.

EQUIPMENT

Laboratory evaluation of the I-NOvent nitric oxide delivery device

J. D. YOUNG, M. ROBERTS AND L. B. GALE

Summary

The "I-NOvent delivery system" (Ohmeda Inc., Madison, WI, USA) is a device designed to add nitric oxide to a ventilator breathing system so that the inspired nitric oxide concentration remains constant in spite of changes in minute ventilation. In a laboratory study the device maintained the inspired nitric oxide concentration delivered to a model lung in the range 10.2–10.7 parts per million (ppm) when set to deliver 10 ppm, and in the range 40.5–42 ppm when set to deliver 40 ppm, for tidal volumes of 500, 700 and 900 ml, ventilator rates of 10, 15 and 20 bpm, peak inspiratory flow rates of 30, 40 and 50 litre min^{-1}, and square, sine and decelerating ramp flow waveforms. (*Br. J. Anaesth.* 1997; **79**: 398–401).

Key words
Pharmacology, nitric oxide. Equipment, breathing systems.

Inhaled nitric oxide is used increasingly to treat hypoxaemia and pulmonary hypertension associated with acute respiratory failure. Most centres in the UK use systems where a continuous flow of nitric oxide–nitrogen mixture is introduced into the inspiratory limb of the ventilator system, but this results in uneven nitric oxide concentrations being delivered during inspiration, and the inspired concentration changes when the patient's minute volume changes. There are only a few systems available for mixing nitric oxide with the inspired gas delivered by a ventilator which maintain a fixed inspired nitric oxide concentration in the face of varying minute ventilation. Two systems are available which only function with specific ventilators, the Nomius "C" for Siemens Servo 900 series ventilators, and the NODomo, for Dräger ventilators. True universal nitric oxide delivery systems, which can work with a range of ventilators or anaesthetic machines to deliver a fixed concentration of nitric oxide independent of minute ventilation or fresh gas flow, have not been available commercially. While we were constructing a prototype device[1] based on a fast-responding mass flow controller, we were aware that Ohmeda were independently developing a more sophisticated device (I-NOvent delivery system) using a similar principle. We report a bench test of the pre-production UK specification prototype of this device.

Description of the I-NOvent delivery system

The I-NOvent delivery system is shown in figure 1 and a diagram of the system is presented in figure 2. The device is mounted on a wheeled plinth which also acts as a carrier for two 10-litre nitric oxide–nitrogen mixture cylinders. Two regulators to reduce cylinder pressure to a lower working pressure are built into the plinth, together with two cylinder pressure (contents) gauges. The device measures inspiratory gas flow with a hot film anemometer placed in the inspiratory limb of the breathing system and delivers the appropriate flow of nitric oxide–nitrogen mixture (1000 ppm of nitric oxide in nitrogen) downstream of the flow sensor with an injector port integral to the sensor housing. The flow of the nitric oxide–nitrogen mixture is controlled with two proportional solenoid valves and monitored with hot film anemometers, effectively forming two

mass flow controllers. Mass flow controllers are devices which control the mass rather than the velocity or volume of gas flowing through them. They are not affected by fluctuations in supply or downstream pressures. The mass of gas passing through can be controlled with an electrical signal. The inspired gas is sampled in the inspiratory limb of the ventilator system approximately 20 cm upstream from the Y piece of the system, and drawn through a water trap before being analysed for nitric oxide, nitrogen dioxide and oxygen concentrations by two electrochemical cells and a fuel cell, respectively. These sensors are for monitoring only, and do not have any effect on the control of nitric oxide delivery.

The front panel contains an electroluminescent screen on which measured inspired nitric oxide, nitrogen dioxide and oxygen concentrations are displayed. The set nitric oxide concentration is also displayed, together with any alarm messages. Calibration, alarms, delivered nitric oxide concentration and display brightness are controlled by seven multifunction push buttons and a single combined rotary/push switch control. The device can deliver nitric oxide 0–80 ppm at ventilator peak inspiratory flow rates below 55 litre min^{-1} and 0–50 ppm at ventilator peak inspiratory flow rates of 55–120 litre min^{-1}.

To allow nitric oxide to be delivered during manual ventilation the device is designed to be fitted with an external oxygen flowmeter, valve and inlet hose. If oxygen is turned on at 15 litre min^{-1}, nitric oxide is added to give a final concentration of 10 ppm. The oxygen–nitric oxide mixture then passes to an outlet which can be connected to a manual ventilation system. The manual system is totally pneumatic and independent of the primary system, and operates even if all power is lost to the device. A battery provides 30 min of backup power.

Test procedure

A Puritan Bennett 7200 ventilator (Puritan Bennett, Hounslow, UK) was used to ventilate a test lung (Lung Ventilator Performance Analyser, BOC Medical, Harlow, UK) set to a compliance of 50 ml cm H_2O^{-1} (510 ml kPa^{-1}) and a flow resistance of 5 cm H_2O litre s^{-1} (0.49 kPa litre s^{-1}). A sampling port was fitted to the test lung, which allowed the concentration of nitric oxide to be measured using an Eco Physics CLD 700AL chemiluminescence analyser (Eco Physics, Dürnten, Switzerland). The flow sensor for the I-NOvent delivery system was placed in the inspiratory limb of the breathing system after the inspiratory filter, the sampling port was placed in the inspiratory limb 20 cm upstream from the "Y" piece.

Flow into and out of the test lung was measured using a TUBA ultrasonic flow measuring device (Transit-time Ultrasonic Breath Analyser, GHG Medical Electronics GMBH, Zürich, Switzerland)[2] and flow of the nitric oxide–nitrogen mixture from the I-NOvent delivery system was measured by inserting a locally made screen pneumotachograph into the delivery tube. Pressure changes across the pneumotachograph were measured using a Validyne 2–0–2 cm H_2O (0.2–0–0.2 kPa) pressure transducer/amplifier (Validyne Engineering Co, Northridge, CA, USA). Flow signals were recorded at 500 samples s^{-1} using locally written software running on a Viglen 386 personal computer (Viglen Ltd, Alperton, UK) and an AT-M10-16 analogue-to-digital converter (National Instruments Ltd, Newbury, UK).

The sequence of ventilator settings was the same as we used previously[1]; in all cases 50% oxygen was used. The tests were performed at nitric oxide settings of 10 and 40 ppm. The ventilator was then set at 10 bpm, peak flow 40 litre min^{-1}, tidal volume 700 ml, square wave profile, and the device tested with nitric oxide settings of 1, 5, 10, 20, 40, 60 and 80 ppm, which are the marked concentrations on the bar indicator that is used to set the nitric oxide concentration.

The integral sensors were calibrated according to the manufacturer's instructions using air as zero for nitric oxide and nitrogen dioxide and 21% standard for oxygen, and nitric oxide 81.5 ppm in nitrogen, nitrogen dioxide 10.4 ppm in nitrogen and 100% oxygen, respectively, as span gases. The calibration gases were supplied by the manufacturer. The chemiluminescence analyser was calibrated using a separate nitric oxide 5.0 ppm standard and checked with the 81.5 ppm standard. The chemiluminescence analyser (in the mode used) has

Table 1 Results are grouped by inspiratory flow waveform. Within each group changes from the base settings of 10 bpm, tidal volume 700 ml and peak inspiratory flow rate of 40 litre min^{-1} are shown in bold type

Table 2 Measured inspired nitric oxide concentrations with the ventilator set at 10 bpm, tidal volume 700 ml and peak inspiratory flow rate of 40 litre min^{-1} over the full range of available nitric oxide settings

Nitric oxide setting on the I-NOvent delivery system (ppm)	Inspired NO (chemiluminescence, ppm)	Inspired NO (built-in sensor, ppm)
1	0.96	1.5
5	5.02	5
10	10	9.3
20	20.1	18
40	40.5	37
60	59.2	55
80	79.4	74

a display resolution of 0.01 ppm, but the results are given to the nearest 0.1 ppm for the 10-ppm tests and 0.5 ppm for the 40-ppm tests as the standard gas mixes against which the analyser was calibrated are prepared to 2% accuracy. The flow sensor for the nitric oxide mixture was tested for linearity and calibrated using a Timeter RT-200 (SLE Ltd, South Croydon, UK) as the standard, and 100% nitrogen as the test gas. The TUBA is self-calibrating, and corrects automatically for gas composition. Nitrogen dioxide concentrations were not recorded from the CLD 700AL because calibration standards have to be prepared in the same gas mixture as the measured gas, and it was not possible to do this accurately.

Results

A total of 42 different combinations of ventilator and nitric oxide settings were tested (table 1). Table 2 shows the results of the linearity test at nitric oxide concentrations of 1–80 ppm. Figures 3 and 4 show the ventilator flow waveforms and the nitric oxide flow waveforms, for the three different inspiratory waveforms tested and for nitric oxide concentrations of 10 and 40 ppm. As the ventilator and device valves opened and closed, transient spikes were observed on the nitric oxide–nitrogen flow trace,

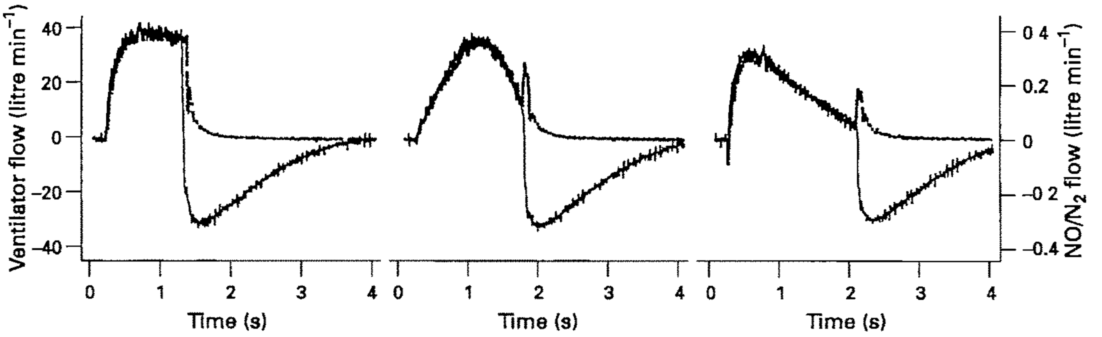

Figure 3 Gas flow measured at the "Y" piece of the ventilator (solid line) and flow of the nitric oxide–nitrogen mixture (broken line) during one ventilator cycle. Positive flow rates are inspiration. The three graphs are for ventilator settings of square, sine and ramp flow waveforms, respectively, with the I-NOvent delivery system set to deliver nitric oxide 10 ppm.

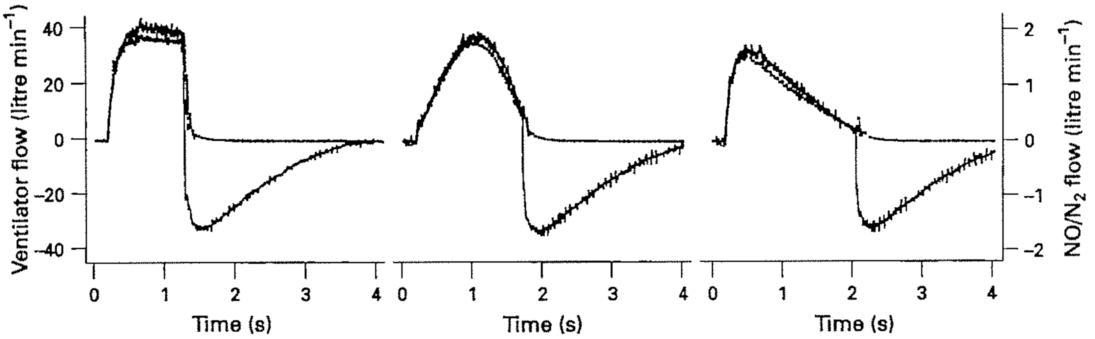

Figure 4 Gas flow measured at the "Y" piece of the ventilator (solid line) and flow of the nitric oxide–nitrogen mixture (broken line) during one ventilator cycle. Positive flow rates are inspiration. The three graphs are for ventilator settings of square, sine and ramp flow waveforms, respectively, with the I-NOvent delivery system set to deliver nitric oxide 40 ppm.

probably caused by the poor frequency response of the pneumotachograph. To partially remove these the nitric oxide–nitrogen flow traces were smoothed with a 41-point running average from the time the valve opened or closed to 80 ms later. The traces are otherwise unaltered.

Discussion

The device appeared to function very well. Control of inspired nitric oxide concentration over a wide range of ventilator settings was excellent, and more precise than is required in clinical use. Its ability to maintain constant nitric oxide concentrations over a range of settings was related presumably to the close matching of the ventilator and nitric oxide–nitrogen flow profiles, which were apparent on the flow traces. To achieve this the flow control devices (and their associated electronics) must have a very fast response time. Although we did not formally measure the response time of the device, the speed of response can be seen clearly on the flow traces at the start of inspiration, when the ventilator flow is changing rapidly. There was virtually no delay in the response of the delivery device.

The built-in nitric oxide meter consistently read lower than the chemiluminescence analyser except at 1 ppm, in spite of correct calibration, but the errors were small and not clinically important. In addition, the resolution of the electrochemical cells was only 1–2 ppm (3% of full scale), so the errors were within the expected range.

The limitations of these tests should be noted. They were conducted at a series of ventilator settings covering commonly used inspiratory flow rates, tidal volumes, rates and waveforms. However, we did not test the extremes of the ventilator capability (for example, the Puritan Bennett 7200 can deliver peak inspiratory flow rates of up to 120 litre min^{-1}), nor did we test the device in any patient-triggered mode (i.e. pressure support). We did not test the device with any continuous-flow ventilators or modes of ventilation, or paediatric ventilators. The absolute accuracy of any measured gas concentrations depends on the standards used, in this case they were within 2% of the nominal concentration.

The technology developed for this device may have other applications in respiratory physiology and experimental medicine. Sulphur hexafluoride injection into the inspiratory gas flow has been used to measure functional residual capacity, and sinusoidally varying concentrations of tracer gases added to the inspiratory gas flow can be used to determine deadspace, alveolar volume and pulmonary blood flow.[3] Until now it was very difficult to perform these measurements in patients undergoing ventilation because reliably adding and mixing tracer gases into the inspired gas is technically challenging. These techniques require careful matching of tracer gas flow to inspired gas flow, which is what this device is designed to do. Continuous measurement of lung volumes and pulmonary blood flow in patients undergoing artificial ventilation may be a useful spin-off from this project.

COMMENTARY

Clinical evidence for delayed chloroform poisoning

C. M. THORPE AND A. A. SPENCE

Summary

From its introduction in 1847, chloroform proved to be a potent anaesthetic agent and over the next 50 yr its use became widespread. However, in 1912 the Committee on Anaesthesia of the American Medical Association stated that they were concerned with the occurrence of delayed chloroform poisoning in a number of cases. This conclusion was based on case reports and experimental animal data. However, subsequent studies and reported series of chloroform anaesthesia in humans have suggested a lower incidence of clinically significant liver injury. In this article we have investigated this discrepancy by analysing the published clinical data relating chloroform anaesthesia to liver damage. (*Br. J. Anaesth.* 1997; **79**: 402–409).

Key words
Anaesthetics volatile, chloroform. History, anaesthesia. History, chloroform.

James Young Simpson discovered the anaesthetic properties of chloroform in 1847[1] and introduced it into clinical practice in Edinburgh. He enthusiastically proclaimed it to be a superior drug to ether. Chloroform proved to be a potent anaesthetic agent and over the next 50 yr its use became widespread throughout the world. However, in 1912 the Committee on Anaesthesia of the American Medical Association pronounced that "The use of chloroform as the anaesthetic for major surgery is no longer justifiable".[2] They were concerned that "delayed chloroform poisoning occurred in a by no means inconsiderable number of cases". At this time, there were no accurate records of the incidence of delayed chloroform poisoning (DCP) and their conclusion was based on case reports backed by experimental animal data. However, subsequent studies and reported series of chloroform anaesthesia in humans have suggested a lower incidence of clinically significant liver injury. We were interested to explore this discrepancy by analysing the published clinical data relating chloroform anaesthesia to liver damage. Information may be divided into three groups: case reports of DCP, large series of chloroform administration and comparative studies.

Case reports

Sheehan published his experience of anaesthesia with chloroform in labouring women.[3] He noted that DCP occurred in patients with severe metabolic derangement after labours of 2–4 days or even longer, and he described the clinical course of illness: day 1: the patient is relatively well; day 2: vomiting occurs, with slight jaundice; day 3: the patient becomes seriously ill with restlessness, delirium, vomiting, upper abdominal pain, increasing jaundice and a low pyrexia; day 4: comatose with "characteristic groaning"; and day 5: deepening coma, increase in temperature and death.

Post-mortem histology showed mid-zonal or centrilobular necrosis of the liver. However, not all patients would develop the full syndrome and die. Davison's description of the clinical illness[4] concurred with Sheehan's account.

In many of the case reports before 1912 it can be seen that the course of illness did not fit that of hepatic damage (table 1). Therein lies one of the major problems of that time: DCP did not have a defined aetiology and clinical pattern. Because of this, a wide variety of causes of death after anaesthesia were attributed to a late poisonous effect of chloroform. Reading the case reports in table 1 it can be seen, for example, that Heyfelders' two cases[5] are convincing histories of liver failure, whereas others such as Guthrie's publications[9 11] indicate other diagnoses.

Bevan and Favill restricted the array of postoperative deaths attributed to chloroform by defining the underlying role of the liver in 1905.[15] They described late chloroform poisoning as a "hepatic toxaemia" causing vomiting, restlessness, fright, mild delirium, convulsions, coma, Cheyne–Stokes breathing, cyanosis and icterus in varying degree. They wrote that death usually ensued, and that fatty degeneration of the liver was seen post mortem. After their review, the term "delayed chloroform poisoning" (DCP) started to appear widely in the literature and the 1912 committee on anaesthesia equated DCP with necrosis of the liver.

C. M. THORPE*, MBBS, FRCA, A. A. SPENCE, CBE, MD, FRCA, FRCPED, FRCS, University Department of Anaesthesia, University of Edinburgh, Edinburgh Royal Infirmary, Lauriston Place, Edinburgh EH3 9YW. Accepted for publication: May 12, 1997.

We found 74 cases in the literature dating from before 1912. The evidence for death secondary to liver failure was very variable in these reports, with jaundice documented in only 20 cases. Frequently the finding of a fatty liver at post mortem was thought to be a sign of death secondary to DCP. In all, only 18 cases stand up to scrutiny as being potential instances of death secondary to liver failure, whereas 35 cases have clinical histories which suggest other causes of death. Twenty-one reports do not have enough information to determine if chloroform could have had an influence on the clinical course.

The case reports published after 1912 (table 2) have a higher proportion of patients with a clinical history compatible with liver failure. We found 49 case reports of patients with DCP in the literature, and 30 of these had documented jaundice. Eighteen patients had a history compatible with liver failure after chloroform anaesthesia, and only four patients had a history which suggested other pathology. In 27 of the 49 reports there was insufficient evidence to form a conclusion.

Large series (table 3)

The three large series published before 1912 had no documented reports of DCP. Snow,[42] Lawrie[45] and Neve[44] had records of 115 550 chloroform anaesthetics in total. Lawrie and Neve practised anaesthesia in India at the turn of the century. They stand out as having safe records of chloroform anaesthesia; however the nature of postoperative care at this time implied that follow-up of their patients was limited.

Between 1948 and 1970 several articles documented the incidence of hepatic damage after chloroform. Eleven authors documented a total of 310 274 chloroform anaesthetics. There were three deaths from liver failure and another six deaths in which it is unclear if the liver was involved. This gives an incidence of fatalities from liver failure of between 1 in 34 474 and 1 in 103 424. Three more patients with severe hepatic damage recovered. The incidence of documented jaundice was 1 in 10 342.

Comparative studies (table 4)

Nine studies comparing chloroform anaesthesia with control (usually halothane) did not show a clinically significant difference in liver damage. Orth[57] found detectable jaundice in six patients compared with three in the control group. However, numbers in these studies were small.

Discussion

Clearly the problem of liver damage after chloroform anaesthesia is not as great as was feared in 1912. A large number of case reports of DCP do not stand up to scrutiny. In many of these, the description is not that of hepatic failure and in those patients who have a reasonable history of liver damage it is difficult to implicate chloroform as the certain cause. However, it does seem reasonable to assume that there is at least some degree of hepatotoxicity in humans. The mechanism by which this may occur has not been elucidated fully, but it is thought to occur via active metabolites after hepatic metabolism of chloroform.[65] Hepatic chloroform degeneration proceeds by cytochrome p450-dependent oxidative pathways, producing reactive metabolites. These are prevented from covalently binding to microsomal proteins by hepatic glutathione (GSH). Phosgene, a reactive metabolite of chloroform, depletes hepatocellular glutathione.[61] The hepatotoxicity of chloroform may therefore be related to two factors: the rate of biotransformation of chloroform into its active metabolites and the availability of GSH to mop up these metabolites. Enzyme induction increasing the rate of metabolism may occur in association with barbiturates, alcohol and severe starvation, and this may explain the possible increase in hepatic damage with chloroform in patients with these conditions. A direct effect of chloroform on the hepatic microsomal calcium pump has also been suggested.[66]

Other causes of liver damage were prominent in the days of chloroform anaesthesia. Hypoxia and hypercapnia cause liver damage, irrespective of the anaesthetic agent used[58] and many anaesthetics were given in which the patient had a poor airway. The lack of supplementary oxygen compounded the problem and it is reasonable to assume that there were many hypoxic patients undergoing the knife. It is worth noting that the excellent safety records of Neve[44] and Lawrie[45] were achieved by anaesthetists who placed great importance on maintaining a clear airway.

In addition, the hepatic effects of chloroform are thought to occur more frequently in those patients with predisposing factors, such as hypoxia, hypercapnia, dehydration and acidosis, and alcoholism. There is no doubt that in the early years of anaesthesia these events were more likely to occur. The possibility of predisposition to liver damage was explored by Ballin in 1903.[12] He reviewed 10 cases of acute yellow atrophy of the liver, eight of which had been given chloroform. He made the point that in every case an inflammatory condition such as appendicitis was present and six of the cases were laparotomies. He thought that this predisposed the liver to the effects of chloroform, and also strongly inferred alcohol as a causative factor.

More recently, others have formed the conclusion that chloroform has had a rough deal. Davison, Wynn and Dykes[55] stated that chloroform was unlikely to produce damage to the liver when used in clinical doses for light anaesthesia. Dykes[67] pointed out that early workers were not successful in proving the existence or determining the incidence of DCP in humans. Davison[4] wrote that chloroform, administered by modern techniques, is no more dangerous than halothane. Strunin[43] analysed the evidence and concluded that chloroform did not entirely fit the criteria required for a drug to be classified as a hepatotoxin. Modern criteria for diagnosing drug-induced hepatotoxicity require stringent investigation. Factors that need to be taken into consideration are the temporal relationship of the disease to starting

Table 1 Case reports before 1912

Author	Date	Operation	Intraoperative course	Postoperative course	Jaundice?	Death	Post mortem
Heyfelder[5]	1847	1. Amputation	Severe cardiovascular depression	Restless, stupor, delirium	Yes	8 days	Nutmeg liver
		2. Amputation	No details	Restless, fever, delirium	Yes	8 days	No details
Casper[6,7]	1862	Amputation	No details	Never recovered senses	No	9 days	No details
Berend[6,7]	1850	1. Removal of shoulder blade	45 min. Stopped three times because of inky coloured blood	Vomiting, small volume, frequent pulse. Venesected	No	17 h	Fatty liver
		2. Amputation	Cried repeatedly on being cut	Generalized spasms	No	No details	No details
		3–10	Not described except for the inky colour of blood				
Bastinelli[7,8]	1890	3 cases	No details	Restlessness, vomiting. Jaundice in one case	Yes	3–10 days	Fatty changes, mostly central in one case
Guthrie[9]	1894	1. Vesical calculus	No details	Screaming, sweaty and cold, t=98F	No	10 h	Normal liver
		2. Aspiration of knee	No details	Screaming, vomiting and restless, t=103F	No	12 h	Pus in kidneys
		3. Genu valgum	1 h	Vomiting and delirium, t=102F	No	27 h	Liver pale and grey
		4. Tapiles equinovarus	Vomited twice	Vomiting, t=101F	No	30 h	Fatty infiltration of the liver
		5. Genu valgum	70 min	Vomiting, delirium, restlessness, coma, t=98F	No	53 h	Small liver
		6. Hydrocele	Took anaesthetic well. Long operation	Collapsed. Excessive vomiting, t=98.6F	No	24 h	Fatty infiltration
		7. Iliac abscess	Chloroform taken badly	Collapsed, vomiting, restless, delirious, t=104.6F	No	6 days	No PM
		8. Iliac abscess	Chloroform taken well. 15 min	Shocked 12 h after operation, t=99.2F	No	14 h	No apparent cause of death
		9. Double psoas abscess	1 h	Crying, vomiting, restless, flushed, t=103F	No	16 h	Fatty liver on section
Brewer[10]	1902	Gangrenous appendix	25 min	Delirium, paroxysms, respiration high, weak pulse, t=103C	No	4 days	Not done
Guthrie[11]	1903	1. TB of knee	None	Vomiting, urine output low, coma	No	3 days	Fatty liver
		2. Webbed fingers	Chloroform taken well	Vomiting, jaundice, unconsciousness	Yes	4 days	Fatty degeneration of the liver
		3. Shoulder naevus	20 min	Vomiting, restlessness, rapid pulse	No	28 h	No details
		4. Posterior pharyngeal abscess	10–15 min. Chloroform taken well	Vomiting, pyrexia, shivering. Became blue	No	33 h	No PM
Ballin[12]	1903	Appendix	25 min. Chloroform tolerated well	Vomiting, jaundice, restlessness, coma	Yes	Recovered	None
Montgomery[13]	1903	Inguinal hernia	Uncomplicated	Restlessness, coma	No	48 h	Liver buff colour
Stiles and McDonald[7]	1904	1. Inguinal hernia	20 min	Restlessness, vomiting, pyrexia, jaundice, rapid pulse and coma	Yes	3 days	Yellow fatty liver
		2. Genu valgum	22 min. Uneventful	Vomiting, restlessness, thirst, rapid pulse, cyanosis, coma, death	No	26 h	Yellow fatty liver. Pneumococcus in lung
		3. Perityphilitis	Necrotic tissue and pus in the abdomen	No details	No	9 days	Fatty degeneration, worse centrally
Steinthal[7]	1896	Fistula of caecum	2 h	Jaundice, rapid pulse, coma	Yes	5 days	No details
Salen and Wallace[7]	1899	1. Laparotomy for salpingo-oophritis	2 h	Jaundice, weakness, rapid pulse	Yes	3 days	Fatty degeneration of the liver
		2. Appendicectomy	No details	No details	No details	2 days	Fatty degeneration of liver, heart, kidneys
Dorner[7]	1899	Hernia	No details	Pyrexia, and "cardiac weakness"	No	42 h	Fatty changes in internal organs
Foerster[7]	1902	1. Osteotomy femurs	50 min	Cardiac weakness and vomiting (black vomit)	No	48 h	Extreme fatty change

Table 1 Case reports before 1912—*continued*

Author	Date	Operation	Intraoperative course	Postoperative course	Jaundice?	Death	Post mortem
Foerster		2. Appendix	No details	Restlessness, vomiting, jaundice, pyrexia, rapid pulse, coma	Yes	5 days	Yellow liver with fatty changes
Carmichael and Beattie[14]	1905	Osteotomy of the elbow	30 min	Restlessness, thirst, vomiting, coma	No	42 h	Enlarged yellow liver. Intense fatty change
Bevan and Favill[15]	1905	Gangrenous ovarian cyst	Prolonged induction and plenty of chloroform	Delirium, increasing pulse rate and temperature. Convulsions	No	110 h	Peritonitis. Fatty liver especially peripherally
Stocker[15]	1895	Strangulated ovarian cyst	No details	Restlessness, icterus, coma, death	Yes	No details	Acute yellow atrophy
Bandier[15]	1896	Incarcerated inguinal hernia	Anaesthesia easily produced	Delirium, jaundice, petechiae, haemorrhage, coma, t=40C	Yes	4 days	Acute yellow atrophy
Marthen[15]	1896	Dental extraction	40 min	Vomiting, restlessness, jaundice	Yes	3 days	Fatty degeneration of the liver
Cohn[15]	1902	Removal of uterine adnexae	Took chloroform well	Restless, vomiting, delirium, coma, jaundice. Pulse 150	Yes	4 days	Icteric nutmeg liver
Erlagh[15 16]	1895	Extirpation of uterus	Bilroths mixture	Icterus, delirium	Yes	No details	Acute yellow atrophy
Thiem and Fischer[7 15]	1890	Removal of blood from knee joint	No details	No details	No details	4 days	Fatty degeneration of the liver
Fraenkel[15 17]	1892	5 cases	2–4 h	No details	No details	40 h–20 days	Fatty changes in the liver in 4 cases
Telford and Falconer[18]	1906	1. Cleft palate	No details	Vomiting, increasing drowsiness, coma, t=102F	No	57 h	Liver canary yellow with fatty degeneration
		2. inguinal hernia	25 min. Chloroform not taken well	Collapse 1st day after operation. Vomiting coffee grounds. Became white and cold	No	1st day	Fatty degeneration in all organs
		3. Osteotomies femur and tibia	15 min	Rapid pulse, restlessness, decreased mental state. Briefly responded to 30 oz saline, then coma and death	No	60 h	Fatty degeneration of the liver
Thorp[19]	1908	Circumcision	Well taken, 7 min	Vomiting, rapid pulse, noisy respiration coma	No	37 h	Not done
Telford[20]	1908	1. Tuberculous	20 min	Vomiting, restlessness, rapid pulse and respiration. No urine output	No	40 h	Yellow liver. Extreme fatty change
		2. Genu valgum	25 min	Restlessness, vomiting, rapid pulse	No	2 days	Extreme fatty change
		3. Inguinal hernia	15 min. Straightforward	Vomiting coffee grounds. Melaena. Yellow tinge to skin	Yes	Recovered	
Bride[21]	1908	1. Tapiles	20 min	Vomiting coffee grounds, rapid pulse, coma	No	32 h	Pale yellow liver. Intense fatty change
		2. Genu valgum	15 min	Vomiting coffee grounds, abdominal pain	No	Recovered	
Wilson[22]	1908	Tuberculous hip	90 min	Nausea, thirst, apathy, restlessness haematemesis	Yes	8 days	Yellow liver with fatty infiltration
Taylor[23]	1908	Inguinal hernia	20 min. Uneventful	Restlessness, vomiting, rapid pulse, coma	No	38 h	Extremely fatty liver
Somerville[16]	1909	1. Genu valgum	ACE mixture	Vomiting, fast pulse and respiration, coma, slight yellowing of skin, t=106F	Yes	20 h	Not done
		2. Twisted ovarian cyst	No details	Vomiting, decreased urine output, rapid pulse, jaundice	Yes	60 h	Central necrosis peripheral fat
		3. Appendicitis	No details	Vomiting coffee grounds, jaundice, rapid pulse, collapse, t=102F	Yes	89 h	Central necrosis peripheral fat
Weir[24]	1909	Appendix 45 min	Uneventful	Restlessness, delirium, coma	No	Recovered	
Payne[25]	1909	3 cases of protracted vomiting.	No jaundice All recovered				
Whipple and Sperry[26]	1909	Incision and drainage chest wall abscesses	35 min. Good anaesthesia and recovery	Vomiting, delirium, restlessness, jaundice, rapid pulse and respiration	Yes	3 days	Extreme central necrosis of the liver
Telford[27]	1910	Pyloric stenosis	No details	Vomiting, restlessness, coma	No	4 days	Yellow liver, extreme fatty degeneration

Table 2 Case reports after 1912

Author	Date	Operation	Intraoperative course	Postoperative course	Jaundice?	Death	Post mortem
Fairlie[28]	1914	Laparotomy	38 min. Protracted induction	Vomiting, dullness, coma	No	77 h	Not done
Stander[29]	1924	Forceps	69 min	Drowsy, restlessness, vomiting, jaundice rapid pulse, cyanosis, t=102F	Yes	3 days	No details
Royston[30]	1925	1. Forceps. 108 h labour	No details	Jaundice, abdominal pain, vomiting	Yes	3 days	Centrilobular and mid-zone necrosis
		2. Craniotomy for fetal hydrocephalus (16 h labour)	No details	Jaundice, impaired consciousness, coma	Yes	Recovered	None
		3. EUA and delivery (24 h labour)	No details	"Abdomen much distended post delivery" Placental bleeding, vomiting, jaundice, coma	Yes	3 days	No details
Gilliat[31]	1928	No details	No details	"5 cases of delayed chloroform poisoning"	No details	No details	No details
Willcox[32]	1931	1. Forceps	No details	Restlessness, jaundice, coma	Yes	4 days	Central necrosis peripheral fat
		2. Appendix	No details	Drowsy, vomiting, jaundice, coma	Yes	5 days	Degeneration of liver cells and fatty degeneration
Stander[33]	1932	Second stage and repair of tear (2 day labour)	30 min	Increasing drowsiness and convulsion	No	3 days	Central necrosis of liver
Todd[34]	1934	Induction for disproportion	No details	Vomiting, drowsiness, rapid pulse coma? slight icterus after death	No	100 h	Central necrosis and fatty degeneration
Gibberd[35]	1935	1. Forceps (48 h labour)	35 min	Vomiting, jaundice, restlessness, coma rapid pulse, t=103F, convulsions	Yes	8 days	Central necrosis and peripheral fatty infiltration
		2. Forceps (30 h labour)	1 h	Jaundice, coma. Pulse 150, t=102F	Yes	5 days	Central necrosis fat peripherally
		3. Forceps	Two anaesthetics "a long time"	Drowsy, jaundice, coma, t=102.4F	Yes	6 days	Diffuse necrosis and peripheral fat
Grant and Miller[36]	1936	1. Manual rotation	30 min	Headache, fever, jaundice, coma, rapid pulse	Yes	7 days	Acute yellow atrophy
		2. Forceps	No details	Vomiting, jaundice. Resolved after 7 days	Yes	Recovered	
		3. Labour	Light chloroform	Developed scarlet fever after operation. Transient jaundice on day 5	Yes	Recovered	
Townsend[37]	1939	1. Forceps, 68 h labour	No details	Jaundice, vomiting, coma	Yes	2 days	Liver necrosis
		2. Second stage labour	No details	Vomiting, jaundice, coma, dilating pupils	Yes	Recovered	None
Sheehan[38]	1939	1. 4 patients with either hyperemesis or vomiting of late pregnancy		Died from either "clinical picture of DCP" and sepsis or from cerebral symptoms	Yes (presumed)	No details	2 gross centrilobular necrosis, 1 centrilobular fat, 1 fat throughout lobule
		2. 8 patients also quoted from other sources. Presumed to have had chloroform, however only documented in 2		No details	No details	No details	Centrilobular necrosis
Sheehan[39]	1940	1. 7 obstetric cases	No details	Jaundice from day 2	Yes	3–5 days	4 mid-zonal tending to centrilobular necrosis, 2 mid-zonal and centrilobular necrosis, 1 mid-zonal necrosis
		2. 2 cases termination for hyperemesis	No details	No details	No details	3–4 days	Centrilobular necrosis
Crawford[40]	1942	5 obstetric cases . All dehydrated and acidotic	No details	3 vomiting, jaundice, restlessness, delirium, 2 milder–just jaundice	Yes	Recovered	None
Marx and colleagues[41]	1962	Laminectomy	5.5 h. Severe blood loss and transfusion at one point	"In distress" followed by sudden stiffening and apnoea	No	2 days	Yellowish liver Mild centrilobular necrosis

Table 3 Large series of chloroform anaesthesia

Author	Date	Number	Incidents	Post mortem
Snow[42]	1858	4000	63 postoperative deaths. No documented jaundice or liver damage	No details
Neve[44]	1898	1. 15 843	2 deaths ?intraoperative. No mention of jaundice or DCP	No details
		2. 78 407	3 deaths, no details	No details
Lawrie[45]	1901	17 300	No mention of jaundice or DCP	
Middleton[46]	1948	1. 3000	As a Japanese prisoner of war. 1 patient with coma and death after 48 h	Acute yellow atrophy
		2. 4500	No fatalities secondary to the anaesthetic	
Gillespie[47]	1950	1111	10 patients with deranged liver function	Recovered
			1 patient died from bronchopneumonia	Fatty degeneration
Lenahan and Babbage[48]	1950	9724	No maternal deaths associated with anaesthesia	
Potter[48]		2500	2 deaths. No details	
Buerger and colleagues[49]	1955	1. 20 000	2 patients with toxic hepatitis	Recovered
		2. 129 530	1 death from delayed chloroform poisoning	No details
		3. 60 000	4 deaths but not specified whether liver involved	No details
Duncan and colleagues[50]	1956	18 302	1 death from fulminating pre-eclampsia. No jaundice	Peripheral necrosis in the liver
Dobkin and colleagues[51]	1960	154	5 patients with pre-existing jaundice. 4 patients developed jaundice:	
			a) 3 h gastrectomy. Developed jaundice and had tarry stool	Recovered
			b) Cholecystectomy. Previous jaundice. Subphrenic abscess and mild jaundice	Recovered
			c) Gastrectomy, Roux en Y. Bronchopneumonia and jaundice	Metastatic cancer Fatty degeneration of the liver
			d) Total colectomy. Transfused. Transient jaundice	Recovered
Siebecker and colleagues[52]	1960	1210	1 death from hepatic damage. Patient had 20–30 m of inadequate ventilation intraoperatively.	No details
Fote[53]	1960	1. 9669 Obstetric	Asymptomatic jaundice in 8 patients	
			1 patient with jaundice, lethargy, hypoglycaemia, convulsion and coma	Recovered
			1 patient with severe pre-eclampsia, pyelonephritis, septicaemia, jaundice and uremia	No details
		2. 199 Obstetric	1 patient developed jaundice	
Whitaker and Jones[54]	1965	1502	1 patient with transient jaundice. ? infectious hepatitis	
Davison[55]	1970	1. 1373	Follow-up limited but no suspicion of jaundice	
		2. 25 307	No liver damage	

Table 4 Comparative studies of chloroform anaesthesia

Author	Year	Study (patient numbers)	Results
Beesly[56]	1906	Chloroform (19) *vs* ether (24) *vs* mixture (3). All with appendicitis.	14 deaths with chloroform, 2 with "delayed poisoning". No jaundice. 2 deaths with ether. 1 death with the mixture of the two.
Orth[57]	1950	Chloroform (65) *vs* other (56)	Detectable jaundice in 6 chloroform patients and 3 "other" patients.
Sims and colleagues[58]	1951	Chloroform (38) *vs* ether (40)	No difference in hepatic injury between anaesthetic agents.
Bamforth and colleagues[59]	1960	Chloroform *vs* halothane (? 100 patients in total)	No liver injury in either group
Jones[60]	1963	Chloroform (29) *vs* halothane (32)	No complications with either group
McReynolds and colleagues[61]	1963	Chloroform (315) *vs* halothane (548)	No difference between groups. 1 patient with chronic liver disease died after 2 anaesthetics—one with each anaesthetic agent!
Griffiths and Ozguc[62]	1964	Chloroform (30) *vs* halothane (27)	No difference in liver enzyme changes
Oduntan[63]	1968	Chloroform (50) *vs* halothane (50)	No problems with either group
Smith and colleagues[64]	1973	Chloroform (58) *vs* halothane (42) *vs* regional anaesthesia (12)	No significant difference in liver function tests except BSP retention higher with chloroform

and stopping the drug, clinical pattern of the illness, epidemiological evidence, exclusion of other causes, assessment for pre-existing liver disease and the result of liver biopsies. Another investigation into causality, the re-challenge test, is too dangerous for routine use. These criteria were obviously not followed during the tarring of chloroform. Many other volatile agents have been implicated in liver damage. Their postulated idiosyncratic role in severe liver damage differs from the direct action proposed for chloroform and is discussed in detail by Ray and Drummond[68] and Elliot and Strunin.[69]

Modern anaesthesia provides accurate delivery of anaesthetic agents, and diligently monitors the airway and cardiovascular status. Given these accepted prerequisites for safe anaesthesia, chloroform does not have a high incidence of clinically significant hepatic damage. The incidence of hepatic failure after chloroform is between 1 in 25 800 and 1 in 51 700 and compares favourably with halothane, which is quoted as 1 in 35 000.[69]

CORRESPONDENCE

Converting pH and H^+: a rule for the other thumb

Sir,—For some 80 yr, inappropriate adoption of Sørensen's pH nomenclature has obstructed ready understanding of biological acid–base relationships. Burden and McQuillan[1] are thus to be congratulated on their championship of the number 83 as an aid to overthrowing obfuscation. It is a pity that an unfortunately misplaced opening parenthesis might lessen the impact of their cunning observation (see erratum notice—editor (p. 413)).

May I try to assist transition to common sense with another observation? An approximation to the pH range of "normal" arterial blood is 7.45–7.35. These values happen to coincide with $[H^+]$ 35 and 45 nmol litre^{-1}, respectively. This coincidence may assist recollection of the nanomolar "normality" range.

Another property of the number 83 occurs to me: quite by chance, simple subtraction of the number 41 gives us the "answer to the great question of life, the universe and everything"[2] ... Silly? Not more so than an inverted scale of positive negative logarithms when simple arithmetic would suffice!

MAC values of mixtures

Sir,—Sharpe and colleagues investigated the effect of desflurane and nitrous oxide anaesthesia on the auditory evoked response (AER), median frequency (F50) and spectral edge frequency (F95).[1] The investigators administered 1.5%, 3% and 6% concentrations of desflurane assuming that 6% desflurane=1 MAC. However, all of their patients received, at the same time, 66% (0.6 MAC) nitrous oxide. Let us assume that 66% nitrous oxide in oxygen=0.6 MAC[2] and 6% desflurane in oxygen=1 MAC.[3] Then, at each time the authors assessed changes in the AER, F50 and F95, the real potency of the anaesthetic mixtures (MAC values), corresponding to 1.5%, 3% and 6% desflurane, are those shown in table 1.

Table 1 MAC values of the anaesthetic mixtures administered

Anaesthetic mixture	MAC value
66% N_2O+6% desflurane	0.6+1=1.6
66% N_2O+3% desflurane	0.6+0.5=1.1
66% N_2O+1.5% desflurane	0.6+0.25=0.85

This highlights some flaws in the methodology of the study. In table 1 of Sharpe and colleagues' study, the authors noted: "Changes in variables for a 1 MAC change in desflurane ...". To which concentration of desflurane are they referring? If they mean 6% desflurane, the real MAC of the anaesthetic mixture is 1.6 MAC. If they are referring to the 1.1 MAC of the mixture, the actual concentration of desflurane in this anaesthetic mixture is 0.5%. For ages 31–65 yr, the addition of 60% nitrous oxide to desflurane reduces the MAC value of desflurane to 2.83%.[3]

It might be better if the authors had evaluated their results as changes in desflurane concentration with concomitant administration of 66% nitrous oxide and avoided the MAC concept. An alternative and perhaps correct presentation of their results might be to calculate the MAC of the anaesthetic mixtures and express these results in terms of MAC values of the mixture.

The MAC of a mixture is simply the sum of the MAC values of its components. The reason that 3% desflurane in 66% nitrous oxide is 1.1 MAC is that 0.5 MAC of the first and 0.6 MAC of the second anaesthetic are given. If more desflurane is given with the nitrous oxide concentration kept constant, the MAC value is increased at a rate of 1 MAC per 6% increase in desflurane concentration. In this study nitrous oxide contributed approximately 0.6 MAC, independent of the desflurane concentrations administered concomitantly.

Sharpe and colleagues found lower F50 and F95 values than those reported by Rampil and colleagues[4] at comparable concentrations of desflurane. However, to which concentrations of desflurane in Rampil and colleagues' study are they referring? In this study, desflurane 0.83, 1.24, 1.66 and 2.0 MAC multiples in oxygen were given to volunteers. Then, an equipotent mixture of desflurane–nitrous oxide was studied in which 60% nitrous oxide was substituted for 3% desflurane. The most likely explanation for the lower F50 and F95 values compared with those of Rampil and colleagues "at comparable desflurane concentrations" may be that the authors ignored the constant presence of nitrous oxide in their study, and the actual potency of the anaesthetic mixture (i.e. 0.85, 1.1 and 1.6 MAC values while administering 0.25, 0.5 and 1 MAC of desflurane, respectively).

One may argue that at equipotent concentrations nitrous oxide has much less effect on the AER compared with volatile agents.[5] Rampil and colleagues also showed that desflurane alone had a more pronounced effect on F50 and F95 than the equipotent desflurane–nitrous oxide mixture.[4] Nevertheless, it is incorrect and confusing to conclude for MAC values of volatile agents alone in the presence of nitrous oxide. The changes in potency in this case, by changing the volatile anaesthetic concentration and keeping constant the nitrous oxide concentration, were not linear.

Sharpe and colleagues claimed that they administered nitrous oxide for comparison with data from their previous studies. One might quantify the effect of 66% nitrous oxide and subtract this from the effect of volatile agent with nitrous oxide, provided that the effects of nitrous oxide on the AER, F50 and F95 are independent of the presence and concentration of the volatile anaesthetic. Another difference from the study of Rampil and colleagues is that Sharpe and co-workers studied patients, not volunteers. Were they studied during or before surgery, as the surgical stimulus may also affect AER, F50 and F95 changes in the opposite direction (less deep anaesthesia)?

5. Thornton C. Evoked potentials. *European Journal of Anaesthesiology* 1991; 8: 89–107.

Sir,—Thank you for allowing us to reply to the concerns of Dr Fassoulaki regarding the MAC additive effect of nitrous oxide. The study aimed to investigate the effect of desflurane on the early cortical AER and the median frequency (F50) and spectral edge (F95) of the EEG. The presence of nitrous oxide was constant throughout and therefore any changes in the above variables were attributed to changes in the concentration of desflurane. It is clearly stated in the title and first sentence of the summary that nitrous oxide was given concomitantly.

The percentage change for each variable with changes in desflurane concentration was calculated from the regression slope of the measured variables. As it is assumed that the addition of nitrous oxide has a MAC additive effect (as pointed out by Dr Fassoulaki) this would simply change the position of the slope on the *Y*-axis and not the regression equation of the slope for a given change in desflurane concentration. We simply used a 6% change in desflurane concentration (equivalent to 1 MAC) for this calculation, so that a similar calculation could be made for equivalent potencies of other volatile agents such as sevoflurane.[1]

The lower median frequency (F50) and spectral edge frequency (F95) seen in our study compared with that of Rampil and colleagues[2] was not because we ignored the addition of nitrous oxide. Rampil and colleagues studied the EEG effects of desflurane in two groups; one with oxygen alone and the other with concomitant nitrous oxide. We compared our data with those of Rampil and colleagues in the nitrous oxide group. For example, Rampil and co-workers demonstrated spectral edge frequencies of 17.1 and 10.6 Hz for 3% and 6% desflurane in nitrous oxide, respectively, whereas in our study the frequencies were 11.2 and 5.5 Hz for the same concentrations of desflurane in nitrous oxide. We have speculated that the lower values for F50 and F95 seen in our study were a result of either age differences or the morphine–atropine premedication given in our study.

To answer the final point, our study investigated patients anaesthetized before surgery to avoid any confounding effects of surgical stimulus which have been demonstrated previously by our group.[3]

The expanding role of simulators in risk management

SIR,—We compliment Professor Spence for his thoughtful remarks in his recent editorial.[1] While we agree with him that "computer screen-based simulators (SBS) ...... are particularly useful for learning alone or at home because they are obviously relatively mobile" we must point out that, although our ACCESS[2] simulator was designed to be mobile and has frequently been moved from hospital to hospital, the need for a real anaesthetic machine, ventilator, operating table and full size manikin makes home use impossible.

Nevertheless, we propose that ACCESS, with its use of full size equipment and the need for the trainee to perform several procedures, for example defibrillation or intubation, makes it a true theatre-type simulator (TTS) and the first of its type to be used in the UK. Although ACCESS cannot compete in terms of technical sophistication with the American designed simulator located in Bristol, it has the advantage of 4 yr of training use in the UK, being within the budget of a single department of anaesthesia (£4000 capital cost *vs* many £100 000's for the Bristol system) and provides a system which can be operated by a single tutor in an existing operating theatre. Although simulations using ACCESS can include other members of staff, for example surgeons and nurses, we have always taken the view that few hospitals have sufficient spare staff to allow this to take place regularly. In view of the evidence that skills are lost within 6 months of training,[3] we feel that to be effective, simulation must be available on a regular (6 monthly perhaps) basis. Although high-fidelity simulators have recently made the headlines, they are too expensive to provide the "training for everyone" that is needed to make anaesthesia safer. While these systems are good for the egos of flagship departments, they are inaccessible to most anaesthetists on a regular basis.

We agree fully with Professor Spence's comments on the use of simulators in assessing the adequacy of a doctor's clinical performance and endorse his view that "to turn away from simulators, or ignore an aspect which obviously some doctors would see as a threat, is not an option". We propose that an anaesthetic simulator such as ACCESS is so reliable and inexpensive that it can be provided in almost every anaesthetic department. Furthermore, we foresee the inclusion of such a simulator as part of Continuing Medical Education.

BOOK REVIEWS

Clinical Anaesthesia. C.L. GWINNUTT. Published by Blackwell Science, Oxford Pp. 378; indexed; illustrated. Price £18.50.

This book aims to provide a comprehensive introduction to the specialty of anaesthesia for medical students and trainee theatre staff. In this it succeeds admirably, filling a gap between long established but dated anaesthetic texts aimed at the student, and the more comprehensive specialist textbooks.

The book is divided into five sections covering general anaesthesia, local and regional anaesthesia, intensive care, chronic pain and cardiopulmonary resuscitation. The section on general anaesthesia is further divided into 12 chapters concerning the conduct of anaesthesia from preoperative assessment to postoperative care. In between the author reviews such subjects as anaesthetic pharmacology, equipment and monitoring. The final section on resuscitation is to be commended and should be mandatory reading for all students before qualification.

All sections of the book are illustrated comprehensively with photographs and line drawings. Important principles are highlighted in text boxes. There is a comprehensive index and each chapter has a further reading list for the interested student.

I have shown this book to several medical students and trainee operating department practitioners; all have rated it highly. Their only reservation has been the price. This is a minor criticism and I would recommend this book to any interested student and indeed to their teachers.

I. McLaren

Textbook of Neuroanesthesia with Neuosurgical and Neuroscience Perspectives. M. S. ALBIN (editor). Published by McGraw-Hill, New York. Pp 1433; indexed; illustrated. Price £122.00.

The editor of this book is a well known senior neuroanaesthetist in North America, and he has invited a team of 76 co-authors, mainly from North America but not exclusively so, to make contributions. The list of authors resembles an edition of "who's who" in neuroanaesthesia. They have produced a very large and highly informative textbook: there are 1433 A4 pages and therefore this is more a reference volume than a handbook.

There are 38 chapters and it was difficult to note any plan in their order. After an interesting first chapter describing the history of neuroanaesthesia, there follows two detailed and informative chapters discussing cerebral blood flow and metabolism, cerebral oedema, intracranial hypertension and intracranial pressure measurement. Three chapters later there is a group of chapters describing monitoring of the brain. After another 10 chapters, which are individual essays on selected topics, there is a section of three chapters related to epilepsy. This is followed by a chapter on stereotactic surgery and then one on electroconvulsive therapy. The book continues in this style with the chapter on paediatric neuroanaesthesia lying between management of acute head injury and neurological intensive care.

Many chapters open with a full discussion of the surgical and medical management of the relevant pathology before discussing the anaesthetic management of the patient. This gives interesting background information, but would probably be of more use to neurosurgeons or neurologists. The title of the book does, however, indicate that this will be a feature of the volume. Discussion of anaesthetic management is obviously based on North American practice, but it is interesting to note the different anaesthetic techniques. Similarly, in the neuroradiology section there are detailed discussions of neuroradiology before there is any discussion of anaesthetic techniques and management of the patient.

I found the last chapter, which discusses brain death, vegetative state, donor management, and the cessation of therapy from an American point of view, very interesting. One difference is their use of atropine 0.04 mg kg^{-1} i.v. to see if there is any vagal activity which can be blocked. One reason for doing a confirmatory test such as EEG is if at least one of the basic tests was not performed by a neurologist, neurosurgeon or a critical care medicine specialist—neuroanaesthetists do not get a mention!

In addition to chapters dealing with topics which one would expect in a textbook of neuroanaesthesia, there are others on neurobehavioural evaluation, consciousness, delirium and coma, and physiological changes with ageing in the central nervous system.

Despite these criticisms, each chapter is detailed, the subject matter is discussed fully and there are large lists of references. The print is easy to read, the figures are clear and the book is well indexed. I doubt if it will be of value to candidates preparing for the Final Fellowship Examination, but I think it would provide interesting reading and a useful source of references in the library of a neuroanaesthetic department, or perhaps of the neuroscience unit as a whole.

Anesthesia and Perioperative Care of the Combat Casualty. R. ZAJCHUK AND C. M. GRANDE (editors). Published by Office of the Surgeon General, United States Army Borden Institute, Walter Reed Army Medical Center, Washington. Pp. 946; indexed; illustrated.

This book is part IV of the *Textbook of Military Medicine* produced by the Office of the Surgeon General, United States Army. The project is a major undertaking and it would appear that the first volume in the series was published in 1989. My first criticism of the book is that it has taken a long time to produce. It is a big, heavy volume that will be appropriate on the shelves of a library. The task, set by the Editor-in-Chief, was to portray the entire expanse of modern combat casualty care. He rightly points out that there is a fundamental difference between combat casualty care in military medicine and trauma management in civilian hospitals.

The initial impression is that this book is well produced. There are 31 chapters to which more than 50 authors have contributed. But the result is a variation in style, repetition and glaring contradictions between chapters. The text is illustrated profusely but most of the truly anaesthetic illustrations have been reproduced with permission from other sources. Some of the illustrations are in black and white, others are in colour; on the whole they are clear and of good quality.

Evidence of how long this book took to produce can be found in the chapter on i.v. anaesthesia. This chapter is particularly disappointing, especially as the authors state that i.v. anaesthetic agents are for many reasons advantageous in the field. There is one reference to an article published in 1989 and none of the remaining 46 references is subsequent to that date. In the chapter on inhalation anaesthesia is the statement that trauma cases may be severely hypovolaemic and that anaesthesia may have to be induced with oxygen, neuromuscular blocking agents and hyoscine before the introduction of inhalation agents. Such statements did not fill this reviewer with confidence!

The American dilemma with anaesthetic machines for use in the field is well demonstrated. When the relevant chapter was written they had no anaesthesia machine with a field ventilator and for medico–legal reasons they were unable to use draw-over equipment in peace-time practice. They relied on full patient monitoring and the supply of compressed gases either from pipelines or cylinders. This was possible in the Gulf War, but is not always achievable near the front line, in Rwanda or Bosnia, for example, or wherever the next military response to aggression will be made.

As in any American textbook there are numerous references. Very few are from books or journals other than US publications. The largest number of references is in one of the intensive care chapters; 252 references which cover 12.5 pages! This particular chapter on syndromes of systemic inflammatory response and multiple organ dysfunction is well written but little is specific to military medicine. The references in the history chapter are particularly infuriating, for example "administration of gas and oxygen (23 references (pp. 649–650))".

Incidentally, reading the history chapter would give the impression that the Royal Army Medical Corps played a minor role in World War 1!

There are two British contributors to this volume, but this book is devoted to the American way; it will serve as an epitaph to US military practice. Much is already obsolete but at least it is recorded, so that lessons of the past do not have to be re-learnt in the future. This is not a pocket book and it is doubtful if a second edition will ever be published. It was conceived by surgeons and written by a heterogenous group of doctors as a major textbook. I fear that it will not be read by many outside the USA unless they are ardent followers of the American doctrine.

Thrombopoiesis and Thrombopoietins: Molecular, Cellular, Preclinical and Clinical Biology. D. J. KUTER, P. HUNT, W. SHERIDAN AND D. ZUKER-FRANKLIN (editors). Published by Humana Press, New Jersey. Pp. 412; indexed; illustrated. Price $150.00.

Over the past 15 yr, the isolation of erythropoietin, followed some time later by granulocyte–monocyte colony stimulating factor (GM-CSF) and granulocyte colony stimulating factor (G-CSF) and their commercial production by recombinant technology, have contributed significantly to the physician's armamentarium, particularly in the fields of nephrology and haematology. In the treatment of haematological and other malignancies, the ready, if expensive, availability of these granulopoietic growth factors, GM-CSF and G-CSF, has enabled new strategies in the chemotherapy of malignant bone marrow disorders, principally the escalation of drug doses with the aim of long-term palliation or cure. With the availability of molecular biology and recombinant manufacturing processes, it has always seemed inevitable that ultimately the third part of the therapeutic jigsaw would fall into place, namely the identification, isolation and commercial production of thrombopoietin, now believed to have a major role in the regulation of megakaryocytopoiesis and platelet production.

This book has, in addition to its four editors, two of whom have industrial backgrounds, one of whom is a scientist and one a physician, and two physicians, 33 other contributors, a small number of whom have scientific commercial roots. The volume is divided into six sections. The first deals with megakaryocyte and platelet physiology with asides into comparative haematology. The second describes in six chapters the history of the research for the physiological regulator of platelet production. The third section details the molecular biology of thrombopoietin, its gene and other transcription factors in megakaryocyte differentiation. The fourth section with five chapters deals with the cellular biology of megakaryocytes, platelets and other cytokines. Section five deals with the preclinical biology of thrombopoietin and finally a sixth part in two chapters deals with what is known of thrombopoietin in health and disease and the regulation of platelet production. It falls short of reporting clinical studies.

The book is well written, adequately illustrated and there is some overlap between chapters but, according to the editors, this has not been removed in order that alternative points of view might be expressed. This text encapsulates a determined search for the third physiological cytokine in haemopoiesis. It cannot be long before thrombopoietin is produced commercially, licensed and available for patients with serious blood disorders and other cancers, and one can foresee its important role developing, particularly in bone marrow transplantation.

ERRATUM

British Journal of Anaesthesia 1997; 78: 479.

The paragraph immediately below the table of Burden and Quillan's letter reads: "To convert pH from H^+, the numerical value of the two digits after the pH decimal point is calculated by subtracting H^+ from 83". The example given is $[H^+]=70.8$ nmol litre^{-1}.

Applying the conversion above:

$pH=7.(83-70.8)\approx 7.12$

and *NOT*

$pH=(7.83-70.8)$ as given, which equals -62.97.

We apologize to the authors for this, which arose during the editorial process.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 79, No.4 OCTOBER 1997

EDITORIAL I

Postoperative respiratory dysfunction: is the site of surgery crucial?

Upper abdominal surgery (UAS) is associated with significant impairment of respiratory mechanics, oxygenation, ventilation and pulmonary defence mechanisms, independent of general anaesthesia.[1] Changes in lung function in such cases are typically restrictive—rapid and shallow breathing, reduced forced vital capacity (FVC) and functional residual capacity (FRC) with consequent hypoxaemia. A shift from abdominal to rib cage breathing has been reported which has been attributed to loss of diaphragmatic contribution to tidal volume.[2] Proponents of upper abdominal laparoscopic surgical techniques have consistently claimed that, by avoiding an abdominal incision, postoperative pain is reduced and recovery of pulmonary function is expedited.[3,4]

In this issue, Joris, Kaba and Lamy describe a study which sought to differentiate the influence of site of surgery, parietal trauma, intraoperative patient position and pneumoperitoneum on pulmonary function and, by extension, to clarify their roles in the pathophysiology of postoperative pulmonary dysfunction.[5] The patient population was female, of normal body mass index and devoid of cardiopulmonary disease. The investigators chose to compare the effects of three types of laparoscopic surgery on effort-dependent measures of lung function, that is forced expiratory volume in 1 s (FEV$_1$), peak expiratory flow rate (PEFR) and vital capacity. Their hypothesis was that surgical trauma, rather than laparoscopy itself, is the primary determinant of postoperative pulmonary dysfunction.

A standardized anaesthetic and similar pneumoperitoneum conditions were used in the three surgical groups. However, inter-group differences in duration of pneumoperitoneum, sites of trocar insertion and patient position were unavoidable. Not expectedly, greater reductions in VC and FEV$_1$ were noted after upper abdominal laparoscopic cholecystectomy procedures. These changes were less than those usually associated with "open" cholecystectomy and the return to normal function was more rapid. Interestingly, there were no significant changes in VC, FEV$_1$ or PEFR after "minor" gynaecological laparoscopy. Pain scores were similar in the three surgical groups. Hence, the authors claim that the site of surgery is an important determinant of lung dysfunction after laparoscopy.

Joris, Kaba and Lamy have made valued and significant contributions to our understanding of the haemodynamic and neuroendocrine consequences of pneumoperitoneum during laparoscopic cholecystectomy.[6,7] This study confirms previous reports of reductions in expiratory lung volumes, FVC, FRC and arterial oxygen tensions after laparoscopic cholecystectomy.[8,9] However, the relevance of this particular study would have been enhanced by a larger sample size and a more comprehensive assessment of pulmonary function. When examining lung function after laparoscopy procedures, one might also consider changes in functional residual capacity (FRC), oxygenation and analgesic requirements.

In common with several other recent reports,[4,10] this study is concerned with maximum inspiratory and expiratory manoeuvres only. In 1973 Tahir and colleagues first suggested that upper abdominal surgery, and more precisely cholecystectomy, inhibits diaphragmatic function.[11] Subsequently, Ford and colleagues[12] demonstrated in 1983 that open cholecystectomy not only reduced maximum inspiratory and expiratory efforts but also modified spontaneous breathing patterns. The contribution of abdominal displacement to tidal volume (V_T) decreased relative to the thoracic component. They attributed these modifications to reflex inhibition of the diaphragm. Furthermore, they suggested that the origin of this diaphragmatic inhibition was afferent nociceptive impulses originating from the chest wall or the internal viscera, or both, after surgical trauma.

With the advent of upper abdominal endoscopic surgery, it was important to assess the impact of these new procedures, not only on maximum inspiratory and expiratory efforts, but also on respiratory patterns during quiet breathing, which are major determinants of gas exchange and may contribute to postoperative hypoxaemia. Couture and colleagues, in a study with significant implications for clinical practice, reported no significant shift from abdominal to thoracic respiration in 10 young patients after laparoscopic cholecystectomy.[13] Functional residual capacity and residual volume remained normal. The investigators concluded that diaphragmatic function remained intact during quiet breathing after laparoscopic cholecystectomy. If this is true, this study confirms the potential patient benefits compared with respiratory changes described previously after traditional "open" procedures.

Pneumoperitoneum creation *per se* might be expected to have adverse consequences for postoperative pulmonary function. The increased intra-abdominal pressure might produce cephalad diaphragm movement, compounding the reduction in FRC associated with general anaesthesia.

However, reassuring observations were reported after a study of seven patients undergoing diagnostic laparoscopy which did not find changes suggestive of diaphragmatic dysfunction.[14]

The site of surgery is a major determinant of postoperative respiratory dysfunction after upper abdominal surgery. The closer the incision to the diaphragm, the greater the reduction in postoperative lung volumes.[15 16] Kum and colleagues recently compared pulmonary function after "French" and "American" techniques of laparoscopic cholecystectomy.[17] There are fundamental differences in port placement in these two techniques. In the French approach, the surgeon stands between the patient's legs, with the ports being inserted in the mid-abdominal region. In the American technique, the surgeon stands to the left of the patient and the ports are concentrated in the right hypochondrium. Both groups were comparable in terms of anaesthetic technique, duration of surgery and degree of surgical trauma. Both FEV_1 and FVC at 6, 24 and 48 h after operation were better preserved in the American group. The authors concluded that the differences were in diaphragmatic dysfunction and in pain site, with similar total pain scores, but a higher location of the pain in the American group. The study by Joris, Kaba and Lamy supports the contention that the site of surgery is an important determinant of the magnitude of pulmonary dysfunction in laparoscopic and also open surgery.

While surgical trauma to the gallbladder is almost identical with open and laparoscopic techniques, it has been suggested that the advantages observed with the latter are related to the minimal trauma inflicted on the abdominal wall. One final caveat might be added; most studies have reported findings from relatively young and otherwise healthy populations. Similar observations after more extensive endoscopic procedures and in patient populations including the elderly, obese and those with co-existing chronic obstructive or restrictive airways disease would be reassuring.

EDITORIAL II

ORG 21465, a new water-soluble steroid hypnotic: more of the same or something different?

The first demonstration of the anaesthetic properties of steroid molecules was in 1927 when Cashin and Moravek produced hypnosis in cats using a colloidal suspension of cholesterol.[1] But it was not until the 1940s that a systematic review was undertaken by Selye into the hypnotic properties of steroids (mainly belonging to the pregnane and androstane groups).[2] Of the screened steroids, there was no apparent relationship between hypnotic (anaesthetic) and hormonal properties; indeed Selye found the most potent anaesthetic steroid to be 5β-pregnane-3,20-dione (pregnanedione), a metabolite of progesterone, that had little endocrinological activity.

Most steroid molecules are poorly water soluble, and little further development was seen until Laubach, P'An and Rudel synthesized hydroxydione in 1955[3] (fig. 1A). This was the 21-hydroxy derivative of 5β-pregnanedione, and was solubilized by esterification at the C_{21} position as the sodium hemisuccinate to give a somewhat unstable solution for i.v. injection. Studies in mice showed that hydroxydione had a high therapeutic index (17.3)[4] and few adverse effects in cats and dogs.[5]

In clinical practice hydroxydione produced minimal changes in cardiorespiratory function, good neuromuscular block, a low incidence of coughing and pleasant recovery, with a very low incidence of vomiting.[6 7] However, induction took several minutes. As there was early obtunding of the pharyngeal and laryngeal reflexes, it was possible to achieve airway intubation without the use of neuromuscular blocking agents. Hydroxydione was also a respiratory stimulant; the rate increasing with an accompanying decrease in tidal volume, leading to an increase in minute volume. Marked respiratory depression and apnoea were not usually seen. Cardiac output and systemic arterial pressure also decreased. There were, however, several unwanted side effects: pain on injection, high incidence of post-anaesthetic irritation at the site of i.v. administration and along the associated vein.

Studies by Robertson and Williams described the use of hydroxydione by continuous infusion.[8] Although they tried several approaches to overcome the thrombophlebitis (dilution of drug solution, premixing with blood, use of large veins), none achieved their goal. In their discussion, the authors surmised that some of the metabolites of hydroxydione might be responsible for part of its anaesthetic activity, particularly molecules with hydroxyl groups at the C_3 position (in place of the ketone) and at the C_{21} position (in place of the attached succinate moiety). This would, of course, have provided an explanation for the delayed onset of action of the steroid, and has been borne out by the more recent studies of Mok, Herschkowitz and Krieger in the mouse.[9]

Despite the limitations of hydroxydione, there has been a determined effort to seek other water-soluble steroid induction agents. Figdor and colleagues demonstrated anaesthetic properties of a series of water-soluble amino-esters based on 21-hydroxy-pregnanedione.[10] Further studies by Hewett and colleagues investigated the animal pharmacology of several androstanes or pregnanes with amino-radicals attached at C_2, C_6 or C_{16}.[11] The most potent in causing loss of righting reflex was 3α-hydroxy, 2β-morpholino, 5α-pregnan-20-one, which had a therapeutic index of 4.7. However, the compound had several disadvantages—long threshold time to onset of anaesthesia and a prolonged duration of effect. Introduction of an 11-keto group shortened the duration of the ED_{50} dose (30 to 17 min) but had little effect on potency.

A second line of investigation was undertaken by Phillips and colleagues who examined a range of steroids where basic side chains were added at

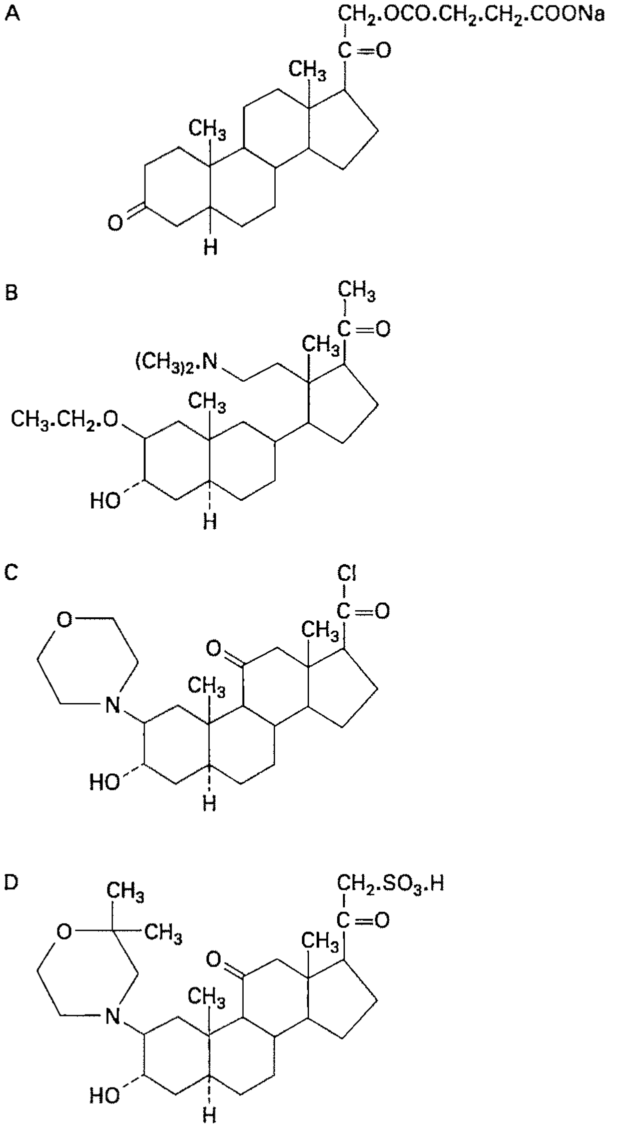

Figure 1 Structures of four water-soluble steroid hypnotic agents: A=hydroxydione; B=minaxolone; C=ORG 20599; and D=ORG 21465.

the C_{11} position.[12] Compounds with 11α or 11β-dialkylaminoacyloxy (or dialkylamino) substituents formed water soluble salts (usually the citrate) which showed anaesthetic activity in mice. Minaxolone citrate was one such steroid, where 11α-dimethyl amino and 2β-ethoxy groups were introduced into the pregnane ring, and the C_3 hydroxyl group was in the α-configuration (fig. 1B). Introduction of the 2β-ethoxy group led to increased potency compared with alphaxalone, while the dimethyl amino group at the C_{11} position in the C ring (in place of the dione group) conferred water solubility. In mice, cats and dogs, minaxolone had a high therapeutic index (>5) and was 2–3 times as potent as Althesin, and eight times as potent as thiopentone.[13] The properties of minaxolone and Althesin appeared similar—less respiratory depression and more rapid recovery than that seen after thiopentone, although there was greater incidence of excitatory movements during anaesthesia in dogs.

Clinical evaluation of minaxolone was carried out in 1251 patients between October 1978 and September 1979. Compared with Althesin, minaxolone had a slower onset of action and a more prolonged recovery.[14–17] The ED_{50} induction dose was 0.52 mg kg^{-1}.[15] When given by incremental dosing to supplement nitrous oxide, the incidence of excitatory movements and hypertonus were greater in patients receiving minaxolone than in the comparator group.[18] The cardiovascular and ventilatory effects of an induction dose of minaxolone 0.5 mg kg^{-1} were similar in magnitude to those after equipotent doses of Althesin.[16 19 20] Both steroids were associated with a low incidence of postoperative nausea and vomiting. When given by continuous infusion, minaxolone infusion rates of 10–15 μg kg^{-1} min^{-1} were needed to supplement 67% nitrous oxide in oxygen anaesthesia.[17] Comparison of the cardiovascular and respiratory effects with those of infusions of Althesin, propofol or methohexitone showed little difference between the four drugs.[21]

Unfortunately, delayed recovery after minaxolone was not its only adverse property. There was also a high incidence of excitatory side effects during induction, increased muscle tone during operation and involuntary movements during recovery, with an overall incidence of approximately 27%, but with a range of 18–45% depending on the premedication prescribed. The incidence of haemodynamic depression was low (3.9% overall), while comparative studies reported a lower incidence of ventilatory side effects than after other i.v. hypnotic agents with the possible exception of etomidate.[18]

Minaxolone also caused two more serious side effects—convulsions during recovery in three patients and abnormal liver function tests after prolonged infusion. In a subgroup of nine patients receiving minaxolone to supplement nitrous oxide for vascular surgery, there were no significant effects on hepatic function in seven of the subjects. However, the other two developed signs of postoperative obstructive jaundice (increases in alkaline phosphatase and serum bilirubin) in the first month after surgery.[22] The aetiology is uncertain, but the jaundice resolved spontaneously in both patients. In September 1979, minaxolone was withdrawn from clinical studies not for clinical reasons but because administration of large doses of the steroid (approximately 100 mg kg^{-1}) to a small number of rats was associated with CNS tumours. This was not supported subsequently by a larger toxicity study involving more than 600 animals.

More recently, two other water-soluble steroid hypnotic agents have been evaluated by Organon Ltd. In 1993, Gemmell and colleagues described the anaesthetic properties in the mouse, rat and dog of a water-soluble 2-morpholino substituted aminosteroid (ORG 20599)[23 24] (fig. 1C). In laboratory animals, this had an efficacy similar to that of Althesin, a high therapeutic index of 13 and was associated with an hypnotic effect of short duration. However, gross excitatory movements in animals, and problems relating to the stability and solubility of the methane sulphonate salt have prevented its evaluation in humans.

Another water-soluble aminosteroid has now been evaluated in both animals and humans (fig. 1D). ORG 21465 (as the base) showed a high therapeutic index of 13.8 compared with values of 4–5 for propofol and thiopentone.[25] In the monkey, ORG 21465 was compared with propofol in doses of 4 and 3 mg kg^{-1}, respectively. Both showed rapid onset of hypnosis, but duration of sleep and recovery was slower with the aminosteroid, while in the dog the effective hypnotic induction dose of ORG 21465 was 3 mg kg^{-1}, and maintenance doses were 2.8 μmol kg^{-1} min^{-1}, giving a potency ratio of 1:8 with respect to propofol. The early clinical data from human volunteers are presented in an article in this issue of the *British Journal of Anaesthesia*.[26]

Doses in excess of 1 mg kg^{-1} caused loss of consciousness within 1 min in unpremedicated male subjects, and the duration of effect was dose-dependent over the range 1.0–1.8 mg kg^{-1}. Preliminary kinetic data indicate rapid clearance from the blood (as we have reported previously for other steroids),[17] but there has been little evaluation of the kinetic–dynamic behaviour of the drug. As with other water-soluble steroids, the authors report a high incidence of excitatory side effects, although there was no accompanying EEG spike activity. Further clinical assessment of ORG 21465 in humans seems unlikely, and we are therefore left to wonder whether it is likely that any steroid anaesthetic agent will have a pharmacological profile superior to other i.v. induction agents presently available.

EDITORIAL III

Meta-analysis: greater than the sum of its parts?

Evidence-based medicine, for physicians, patients and purchasers, is revolutionizing medicine in the late 20th century. While the fundamental principles are easy to grasp, much of the surrounding jargon can be confusing. Perhaps one of the most intimidating of all is the term "meta-analysis". The prefix *meta-* is defined by the *Shorter Oxford English Dictionary*[1] as "denoting a nature of higher order or more fundamental kind". Are we thus dealing with a highly complex technique understood only by the chosen few? The answer, of course, is no. Simply stated, meta-analysis is the process of quantitatively combining the results of several research studies on a particular topic to answer a specific question.

A conscientious practising clinician will regularly review the general and specialist literature in their field in order to ensure that the decisions they take and the care they give is the best available. Meta-analysis can be viewed as a systematic extension of this process of locating, assessing, interpreting and drawing conclusions from the ever-expanding body of research output. It is a secondary form of analysis of a set of primarily reported data, but it must still adhere to strict methodologies of approach to avoid the problems inherent in the combination of multiple studies. Rather than being a "vote" on a topic by simply counting studies for and against, the meta-analysis should aim to discriminate between, and weight studies, based on their power and quantitative result.

The following steps detail how a systematic review should be performed, but also highlights points whereby the discerning reader may appraise the validity of meta-analysis.

As with all research, the first step is to formulate the question. There must be a clear definition of the problem concerned and the "terms of reference" involved in order to identify what studies are relevant and qualify for inclusion in the overall analysis. This also aids the reader in later defining the contextual relevance of the meta-analysis to their own practice.

Systematic searching for all relevant research is essential. Computer searching of the common medical publication databases must be done in a structured way to ensure that all relevant articles are discovered. Automated searching can only be taken so far, however, and hand searching of the most relevant journals has been shown to detect many more articles than electronic searching.[2] Studies with negative or null findings are less likely to be written up, submitted or published than positive results, and thus it is vitally important not to restrict the review to published material.[3] A typical example may be the seeming ability of an anaesthetic agent to reduce the incidence of postoperative nausea and vomiting. A limited number of small weakly positive studies would seem to indicate a treatment effect. However, several adequately sized studies have illustrated a lack of effect. Were these to be included in a meta-analysis it would be apparent that there was no treatment effect. However, the publication bias results in only the positive studies reported and a spurious conclusion when these are considered in a systematic review. Consulting registers of clinical studies, large funding agencies and prominent researchers in the field are ways of ensuring that *all* relevant studies are considered.

Incentives are on hand to improve this process, most notably the Cochrane Collaboration[4] which exists to prepare, maintain and disseminate systematic reviews and meta-analyses. The Collaboration also co-ordinates and maintains a register of randomized, controlled studies, developed using electronic searching, hand searching of journals and conference proceedings, and from prospective study registries.

When as complete a set of reports of potentially relevant research studies as possible has been gathered, they must then be assessed for inclusion by strict criteria, ideally by using at least two referees to offset bias of interest.

(1) Studies should be randomized and controlled. Methods for combining observational comparison studies where the risk of bias is much higher are in their infancy, and at present the analysis of such data presents unresolved complexities that preclude acceptable presentation.

(2) There should be exact definitions of the treatments compared and the methods of comparison.

(3) Outcome data should be identified clearly.

(4) Each study should be assessed for any individual characteristics of its methodology that may influence and bias outcome. This may occur at any of four stages.

(a) Selection bias at study entry—when the randomizing clinician is aware of the treatment to which the next patient will be allocated and then excludes (possibly unconsciously), "unsuitable" patients.

(b) Performance bias—where two arms in a study are treated differently apart from the therapy or effect under study. For example, patients receiving opioids parenterally as opposed to orally, in a study of analgesic side effects are given other drugs i.v. also, which may induce hypotension when administered by that route.

(c) Exclusion and compliance bias—when subjects are non-compliant, lost to follow-up or excluded from analysis differentially between the treatment arms. For example, an active daily oral treatment may have substantial adverse side effects and lead to much lower compliance than a placebo control arm.

(d) Assessment bias—where outcome and effect are assessed by a researcher aware in some manner of group allocation, that is there has been a failure of observer "blinding". For example a new sedative given to patients in an ICU turns urine pink by virtue of a pharmaceutical congener effect which is absent from the control group.

Nurses involved in scoring sedation levels notice the difference.

Having selected the studies, the meta-analysis must then quantitatively combine estimates of effect, commonly given as either *odds ratios*, *relative risks* or *risk differences* for the risk of some event. Odds ratios are the most common measure of association, being a ratio of the odds of effect/non-effect in a treatment group compared with the odds in a control group. In low incidence events, this equals the relative risk, but where the incidence is higher the two measures diverge. An alternative means of summary description is the "number needed to treat (harm)". This is intuitively simple, just being the number of patients which would need to be given the active treatment in order to prevent (cause) a single adverse event. For example, for every 122 patients receiving a blood substitute, one will experience an anaphylactic reaction; the number needed to harm (NNH) is 122. Note that this figure is not of value in itself, but is for use in comparison with competing treatments for the same condition, and in a public health context between differing conditions.

One of the main questions (some would say dilemma) at the analysis stage is whether or not there is ***homogeneity of effect*** across the included studies. If so, a ***fixed effects model*** where the treatment effect is assumed to be ***constant*** is appropriate. Otherwise, a ***random effects model***, where the treatment effect can *vary* from study to study about an overall "average" effect is preferable. Whichever model is used, the final summary statistic is a measure of effect size and an associated confidence interval, with narrower intervals indicating increasing degrees of precision of results.

Obviously, conclusions made in the meta-analysis should be based on the data analysed and should not be coloured by the views of the authors. The key question that should be asked is "How universal are the results?" Did the review consider the treatment in all possible patients, or in a small subgroup? Were the effect sizes observed in the individual studies homogenous, and if not *why* not? Often similar studies compare therapies in patients at widely varying baseline risk, and it can be useful to plot the outcomes of the control group against the observed effect size. Is it reasonable to expect the treatment to have similar effects across all levels of risk?

Sensitivity analysis[5,6] is one method which can attempt to answer some of these problems. By including only randomized studies or studies on a particular subgroup of patients, the dependence of the conclusions on the assumptions made during the analysis (homogeneity of effect across all subgroups, similar populations, etc.) can be assessed. One example of this is the discrepancy sometimes observed between meta-analyses of the small studies and the large studies in the same area. Protocol variations frequently occur between centres and studies, in the real world. Meta-analyses that include a large number of small studies as opposed to a small number of large studies are more prone to such problems, which may lead to disagreements between overall similarly sized meta-analyses. Consider studies on the effect of extradural anaesthesia on the duration of the second stage of labour. Simple differences in obstetric practice between a large number of centres (e.g. the timing of vaginal examinations) may lead to wide variations in the accuracy of detection of the stages of labour in these small studies and significantly influence the end result. This effect may not occur in one or two large single centre studies, where consistent protocols of practice are in place. This is not to say that such multicentre reviews are flawed, merely that the results must be interpreted with these cautions in mind.

Finally, several authors have suggested that one of the most useful pieces of information to report about a meta-analysis is the total size of a study (or studies) which would need to be discovered in order to substantially change the conclusions of the meta-analysis.[7]

In conclusion, meta-analyses will never remove the need for large, multicentre, randomized, controlled studies. They are, however, invaluable for summarizing the often conflicting results of similar studies, and as part of the planning process for new research. Indeed, several major funding agencies now regard the completion of a systematic review of the evidence as a prerequisite stage in the planning of a randomized clinical study. Meta-analysis is not magic, however, and behind all the jargon is simply a research process. Good meta-analysis is founded on good science, and poorly conducted research studies cannot be fixed retrospectively. The onus is still on the primary researchers to design, conduct and report high quality studies and thus provide more grist for the meta-analysis mill.

CLINICAL INVESTIGATIONS

Postoperative spirometry after laparoscopy for lower abdominal or upper abdominal surgical procedures†

J. Joris, A. Kaba and M. Lamy

Summary

In this prospective study, we have compared women undergoing laparoscopic cholecystectomy, laparoscopic gynaecological surgery and laparoscopic minor gynaecological procedures (diagnostic, tubal ligation) (n=10 in each group) to determine if lower abdominal laparoscopy results in less postoperative pulmonary dysfunction than upper abdominal laparoscopy. Pulmonary testing was performed before operation, and 3 and 6 h after operation, on the first and second days after surgery. After operation, a significant reduction in forced vital capacity, forced expiratory volume in 1 s and peak expiratory flow rate occurred after laparoscopic cholecystectomy at each time. There were no significant changes after minor gynaecologic laparoscopy, whereas laparoscopic gynaecological surgery resulted in minor pulmonary dysfunction on the day of surgery only. We conclude that postoperative pulmonary function was less impaired after gynaecological laparoscopy than after laparoscopic cholecystectomy. This study suggests that the site of surgery is an important determinant of lung dysfunction after laparoscopy. (*Br. J. Anaesth.* 1997; **79**: 422–426).

Key words
Surgery, gynaecological. Surgery, laparoscopy. Lung, function.

Upper abdominal surgery performed via laparotomy is associated with postoperative respiratory changes, including a restrictive syndrome (reduced vital capacity and functional residual capacity), hypoxaemia, a change from abdominal to rib cage breathing and increased work of breathing. The site and size of incision,[1 2] postoperative pain[1 3] and diaphragmatic dysfunction[4–6] are the main factors contributing to the pathogenesis of these postoperative respiratory changes.

Laparoscopy, which avoids large abdominal incisions, allows a significant reduction in surgical trauma, postoperative pain and opioid requirements.[7–10] Laparoscopic cholecystectomy also results in less postoperative pulmonary dysfunction,[7 9–13] faster recovery of preoperative pulmonary function[12] and less atelectasis and hypoxaemia[11 12] than open cholecystectomy. Nevertheless, postoperative pulmonary dysfunction after laparoscopic cholecystectomy is significant. The role of inflammation of the punctured abdominal wall or gallbladder bed, or both, carbon dioxide pneumoperitoneum or intraoperative patient position in the pathogenesis of this pulmonary dysfunction is unknown. In all of these studies, pulmonary function was evaluated after laparoscopic cholecystectomy. Few data are available after lower abdominal surgical procedures, such as laparoscopic gynaecological surgery, or after minor laparoscopic procedures such as diagnostic laparoscopy or tubal ligation. Such data may be useful to differentiate the influences of the surgical site, parietal trauma, intraoperative position and pneumoperitoneum in the pathogenesis of pulmonary dysfunction.

Therefore, we have compared changes in pulmonary function after laparoscopy for cholecystectomy, gynaecological surgery and minor gynaecological procedures, such as diagnostic laparoscopy or tubal ligation.

Patients and methods

The study was conducted after obtaining approval from our institution's Ethics Committee and informed patient consent. We studied 30 consecutive women undergoing elective laparoscopic cholecystectomy (group Chol.), laparoscopic gynaecological surgery (group Gyn.) or laparoscopic minor gynaecological procedures (group Min.) (10 in each group). Inclusion criteria were body weight no more than 20% over ideal weight, age between 18 and 60 yr, absence of acute cholecystitis or pelvic inflammatory disease, and no cardiorespiratory disease or medications.

ANAESTHESIA

We used the same anaesthetic technique in all

groups. All patients were given hydroxyzine 50 mg orally, 2 h before surgery, and an i.m. injection of midazolam 5 mg and atropine 0.25 mg before transfer to the operating theatre. Anaesthesia was induced with sufentanil 15 μg and propofol 2 mg kg^{-1}. After tracheal intubation facilitated by atracurium 0.5 mg kg^{-1}, general anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen. Minute ventilation was controlled (Servo 900C, Siemens-Elema) and adjusted to maintain the end-tidal partial pressure of carbon dioxide at 4.0–5.0 kPa. During laparoscopy, intra-abdominal pressure was maintained automatically at 14 mm Hg by a carbon dioxide insufflator. At the end of surgery, residual neuromuscular block was antagonized with neostigmine 40 μg kg^{-1} and atropine 15 μg kg^{-1} i.v.

ANALGESIA

Pain intensity was measured using a 100-mm visual analogue scale at 3, 6 and 24 h after surgery. Treatment of postoperative pain was provided on the same nursing unit using a standardized regimen in all groups. During the first 24 h after operation, propacetamol 2 g, a precursor of paracetamol (Prodafalgan, UPSA Medica, Brussels, Belgium: propacetamol 2 g=paracetamol 1 g) were given i.v. every 6 h as necessary. If pain relief was considered inadequate (pain score >40 mm on a 100-mm visual analogue scale at rest) piritramide 0.2 mg kg^{-1} (Dipidolor, Janssen Pharmaceutica, Beerse, Belgium), a synthetic opioid, was administered i.m. On the second day, paracetamol 1 g with codeine phosphate 60 mg (Dafalgan codeine, UPSA Medica, Brussels, Belgium) were given orally at the patient's request every 6 h.

SURGERY

For all procedures, the laparoscope was introduced via a 10-mm diameter umbilical port. Laparoscopic cholecystectomies were performed using three additional trocars, one 10-mm and two 5-mm diameter ports, located in the right and left subcostal area, and the epigastric notch. For gynaecological laparoscopies, two trocars, one 10 mm and one 5 mm in diameter, were placed in the hypogastric region in addition to the umbilical port. Patients were tilted to the 10° head-up position for laparoscopic cholecystectomy and to the 20° head-down position for gynaecological laparoscopy. Care was taken to expel a maximum volume of gas from the abdominal cavity at the end of all laparoscopies.

PULMONARY FUNCTION

Pulmonary testing was performed in the sitting position by the same technician, who was unaware of the patient group, the day before surgery, and 3 and 6 h after surgery on days 1 and 2 after operation (except in group Min.; these patients were discharged on day 1). The following variables were recorded: forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1) and peak expiratory flow rate (PEFR). These variables were measured using a Microlab 3000 series bedside spirometer (Micro Medical Ltd, Rochester, England).

STATISTICAL ANALYSIS

Results are expressed as mean (SEM) except in table 1 where SD values are used. Data were analysed by analysis of variance followed by Scheffé's test for multiple comparisons. Results were considered to be statistically significant at the 5% level.

Results

Patient data and preoperative pulmonary function were similar in the three groups (table 1). In group Gyn., two patients underwent laparoscopically assisted vaginal hysterectomy, one had bilateral oophorectomy and the other seven had unilateral oophorectomy. In group Min., three women had diagnostic laparoscopy and the others had tubal ligation. Duration of pneumoperitoneum for cholecystectomy was significantly longer than for the other procedures, whereas duration of pneumoperitoneum in group Gyn. was longer than in group Min. (table 1). Pain intensity was similar in the three groups (table 2).

FVC, FEV_1 and PEFR did not change significantly after minor gynaecological laparoscopy. After laparoscopic gynaecological surgery, FVC and PEFR decreased significantly, but only on the day of surgery (19% and 29%, respectively), whereas no significant changes in FEV_1 were observed. After laparoscopic cholecystectomy, FVC, FEV_1 and PEFR decreased significantly at all times, except on day 2, when FEV_1 was no longer different than the preoperative value. In this last group, FVC, FEV_1 and PEFR reached their lowest values 3 h after

surgery, and subsequently increased. The increase in FVC became significant relative to 3 h on day 1, and on day 2 for FEV_1. FVC, FEV_1 and PEFR were significantly lower in group Chol. than in the two other groups. FVC and FEV_1 in groups Min. and Gyn. did not differ significantly. PEFR in group Gyn. was significantly reduced compared with group Min. at 6 h after operation (figs 1–3). There were no correlations between duration of pneumoperitoneum and changes in FVC, FEV_1 or PEFR at any time.

Discussion

This study suggests that laparoscopy for lower abdominal surgery resulted in minor postoperative pulmonary dysfunction on the day of surgery only. Furthermore, these changes were less severe than those after upper abdominal laparoscopic surgery. Also, carbon dioxide pneumoperitoneum with minimal or no surgery, such as for diagnostic laparoscopy or tubal ligation, and Trendelenburg position did not produce significant changes in pulmonary function.

This study confirms the development of a restrictive pulmonary syndrome after laparoscopic cholecystectomy. Not only expiratory lung volumes,[7 9–13] but also functional residual capacity are reduced after laparoscopic cholecystectomy.[9 11 13] Postoperative atelectasis on chest x-ray, and decreases in Pa_{O_2} have also been reported.[11 12] In addition, changes in respiratory pattern, characterized by shallow breathing at a faster rate, were noted after laparoscopic cholecystectomy.[14 15] Therefore, although laparoscopic cholecystectomy is associated with better postoperative lung function than open cholecystectomy,[7 9–13] the patterns of alteration after cholecystectomy are qualitatively similar irrespective of the surgical approach. Consequently, the pathogenesis of pulmonary dysfunction observed after open and laparoscopic cholecystectomy should also be similar.

Pain contributes to impairment of pulmonary function after open upper abdominal surgery.[13] Several studies, however, failed to demonstrate clinically significant benefits (in term of improved rate of postoperative pulmonary complications) of extradural analgesia compared with conventional systemic opioid analgesia, despite better pain relief.[16 17] Similarly, extradural analgesia did not improve lung dysfunction after laparoscopic cholecystectomy.[18] Minor gynaecological laparoscopies are associated with a similar degree of trauma to the abdominal wall, as ports of similar sizes were used in these procedures. Moreover, laparoscopic tubal ligation, although considered to be a minor procedure, frequently results in severe pain.[19] Accordingly, similar pain intensities were reported by patients in the three groups. Nevertheless, in our study minor gynaecological laparoscopies resulted in no significant changes in pulmonary function. Similarly, laparoscopic hernia repair produces no postoperative ventilatory impairment although the same number of incisions are performed, in close proximity to the abdominal regions involved in laparoscopic cholecystectomy.[14] Therefore, pain, and more particularly incisional pain, does not seem to play a major role in the lung dysfunction noted after laparoscopy.

Whereas surgical trauma to the abdominal wall and the type of incision have been proposed as important causes of pulmonary dysfunction after open upper abdominal surgery,[1 2] Ford and colleagues showed that a reduction in diaphragmatic performance was the main determinant of impaired lung function.[4] Several clinical and experimental studies have suggested that diaphragmatic dysfunction possibly results more from reflex inhibition of efferent phrenic nerve activity secondary to irritation of splanchnic afferents, than from contractile failure of the diaphragm or surgical trauma to the abdominal wall.[4–6 20 21] After laparoscopic cholecystectomy, functional diaphragmatic impairment has also been documented.[14 15] Diaphragmatic electromyography using electrodes implanted in the diaphragm during surgery confirmed diaphragmatic dysfunction in the early postoperative period.[22 23] The magnitude of this dysfunction appears, nevertheless, to be less than that after open cholecystectomy.[15] Impairment of intrinsic diaphragmatic contractility after laparoscopic cholecystectomy has also been excluded.[14] Inflammation of the punctured parietal peritoneum, peritoneal inflammation secondary to carbon dioxide pneumoperitoneum, residual carbon dioxide accumulated under the diaphragm after operation and inhibitory reflexes arising from the gallbladder bed are all potential causes of diaphragmatic dysfunction after laparoscopic cholecystectomy. The lack of an effect of extradural analgesia on the restrictive syndrome after laparoscopic cholecystectomy excludes nociceptive abdominal stimuli as major determinants of diaphragmatic dysfunction.[18]

Moreover, in this study gynaecological laparoscopic surgery produced no or only minor postoperative pulmonary impairment despite similar trauma to the abdominal wall and a similar postoperative pain intensity compared with laparoscopic cholecystectomy. Although the extent of abdominal wall trauma was similar, the sites of trocar insertion were different for gynaecological laparoscopy and laparoscopic cholecystectomy, and might therefore contribute to differences in pulmonary function observed after these laparoscopic procedures. Nevertheless, Erice and colleagues did not observe diaphragmatic dysfunction after laparoscopic inguinal hernia repair, although sites for trocar insertion for laparoscopic hernia repair and cholecystectomy involved the same abdominal region.[14] These observations exclude parietal trauma as a possible source of inhibitory reflexes. The longer duration of pneumoperitoneum might be responsible for the more intense pulmonary dysfunction observed after laparoscopic cholecystectomy.[24] However, we did not observe a significant correlation between duration of pneumoperitoneum and any of the spirometric variables measured. The position of the patient may induce changes in lung volumes. Whereas the Trendelenburg position reduces functional residual capacity (FRC) and vital capacity in anaesthetized spontaneously breathing volunteers, the head-up position increases FRC.[25] Thus postoperative lung volumes might be expected to be affected more after laparoscopic procedures in the head-down position.[26] However, there were no significant changes in lung function in group Min. In addition, carbon dioxide pneumoperitoneum alone, such as for diagnostic laparoscopy, does not impair diaphragmatic function.[27] Accordingly, we did not observe pulmonary dysfunction in patients undergoing minor gynaecological laparoscopy. Therefore, the intra-abdominal site of surgery itself appears to be the main determinant of diaphragmatic inhibition after laparoscopic abdominal surgery,[14] as seen in open surgery.[28] The exact reflex neural pathways that cause this dysfunction need to be defined. Experimental data suggest that afferents for reflex inhibition of phrenic output possibly originate in the coeliac sympathetic plexus or other upper abdominal sympathetic ganglia.[20 21]

Taken together, these observations raise the question of the mechanism(s) accounting for the less severe lung dysfunction seen after laparoscopic cholecystectomy compared with open procedures. During laparoscopy, the most apparent reduction in surgical trauma results from the absence of large abdominal incisions. Consequently, postoperative pain, more particularly during mobilization and coughing, is less after laparoscopy.[29] Moreover, whereas incision of the abdominal wall results in persistent pain after laparotomy, pain after laparoscopy is more short-lived.[30] Finally, visceral pain accounts for most of the pain experienced after laparoscopic cholecystectomy, compared with parietal pain which is predominant after open cholecystectomy.[7] These changes in pain characteristics may explain why the contribution of incisional pain to the respiratory restrictive syndrome after laparoscopy is insignificant. Visceral trauma, the main determinant of postoperative diaphragmatic dysfunction, would be expected to be unchanged whatever the surgical approach. Nevertheless, handling and dissection of intra-abdominal viscera are more gentle during laparoscopy, probably leading to less visceral trauma. The consequent visceral inflammatory reaction might be reduced compared with open surgery. In support of this concept, it is notable that postoperative adhesions are less after laparoscopy compared with laparotomy.[31]

Administration to humans of ORG 21465, a water soluble steroid i.v. anaesthetic agent

J. R. SNEYD, P. M. C. WRIGHT, M. CROSS, P. THOMPSON, G. VOORTMAN, M. M. WEIDEMAN, C. J. H. ANDREWS AND C. J. DANIELL

Summary

Ten male volunteers received a 1-min i.v. infusion of a new water soluble steroid anaesthetic agent, ORG 21465. Individuals received doses ranging from 0.8 to 1.8 mg kg^{-1}. All subjects experienced venous pain at the site of injection; those receiving 1.0 mg kg^{-1} or more became anaesthetized. There was no evidence of histamine release and apnoea did not occur. Excitatory phenomena were observed in all subjects and were dose related; no spikes were seen on the EEG. Pharmacokinetic analysis supported a three-compartment (non-weight-related) model with compartmental volumes V_1, V_2 and V_3 of 4.31, 14.2 and 89.4 litre, respectively. Clearance from the central compartment V_1 was 1.55 litre min^{-1}. Inter-compartmental clearances $\dot{Q}_1$ and $\dot{Q}_2$ were 2.54 and 1.79 litre min^{-1}. We found that ORG 21465 was an effective anaesthetic in humans. The relationship between sedation, anaesthesia and excitation requires further exploration. (*Br. J. Anaesth.* 1997; **79**: 427–432).

Key words

Anaesthetics i.v., steroid. Sedation. Pharmacology, ORG 21465. Pharmacokinetics, ORG 21465.

The anaesthetic properties of some steroids were described in animals in 1941 by Selye[1] and we now know that the likely mechanism of action is interaction at specific sites on the $GABA_A$ protein and the $GABA_A$ chloride channel complex.[2] Several different compounds of this type have been evaluated as anaesthetic agents in humans but problems with solubility, pain on injection and slow induction or recovery have often been a feature.[3 4] Some agents have reached clinical practice (notably minaxolone,[5] Althesin[6–8] and eltanolone[9–13]) but have subsequently been withdrawn because of toxicity problems.[14]

Recently, ORG 21465, a water soluble preparation of (2β, 3α, 5α)-3-hydroxy-2-(2,2-dimethylmorpholin-4-yl) pregnane-11,20-dione, has been identified as an anaesthetic and tested in some animal species (fig. 1). In voltage-clamped *Xenopus* oocytes expressing human recombinant $GABA_A$ receptors, ORG 21465 enhanced the inward current response evoked by GABA in a concentration-dependent and reversible manner.[15] The EC_{50} for this potentiation process was 2.3 μmol $litre^{-1}$; those for propofol and thiopentone are 2.2 and 3.8 μmol $litre^{-1}$, respectively. In preclinical testing, bolus injections of ORG 21465 were given to mice, rats, pigs and dogs. The dose required to produce sleep in mice was similar to that of other steroids. Mice given $2 \times ED_{50}$ doses of ORG 21465 slept for an average of 3.7 min; those given similar doses of alphaxalone, propofol and thiopentone slept for 1.7, 3.1 and 4.1 min, respectively.[15] The therapeutic index (LD_{50}/ED_{50}) of ORG 21465 for mice was 13, while those of alphaxalone, propofol and thiopentone were 23.7, 3.6 and 3.7, respectively.[15] In pigs and dogs, ORG 21465 acted as a potent, smooth, short duration anaesthetic.[15] We considered that ORG 21465 might be an effective and safe i.v. anaesthetic in humans and this study reports observations from the first 10 administrations to humans.

Subjects and methods

SCREENING AND PREPARATION OF SUBJECTS

We selected 10 healthy male volunteers, aged 22–28 yr, weighing 63–98 kg, after a preliminary screening process involving physical examination, treadmill exercise testing, echocardiography, haematological and biochemical screening. All subjects were within 15% of ideal weight for height and age, and had previously experienced general anaesthesia without incident. All subjects gave

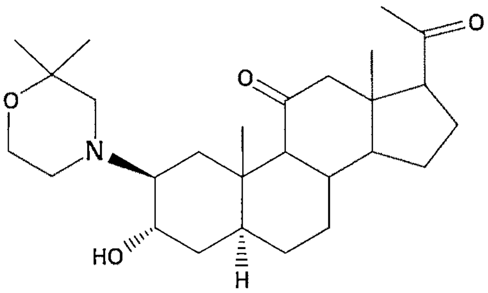

Figure 1 ORG 21465 is a water soluble preparation of (2β, 3α, 5α)-3-hydroxy-2-(2,2-dimethylmorpholin-4-yl) pregnane-11, 20-dione. Preclinical testing in mice, rats, dogs and monkeys indicated that ORG 21465 appeared safe and might be a suitable i.v. anaesthetic in humans.

written informed consent and the study was approved by the local Ethics Committee.

Subjects were admitted to hospital the night before drug administration and underwent another physical examination and urine screening for drug abuse or alcohol (Merck Triage kit). Subjects were starved from 22:00 and permitted to drink water until midnight. At 06:00 an infusion of Hartmann's solution at a rate of 3 ml kg^{-1} h^{-1} was commenced into the dominant forearm.

The study took place in a large room divided by a partition: the subject, two anaesthetists, an anaesthetist's assistant, a nurse taking blood samples and the camera operator were in one half of the room with essential anaesthetic and resuscitation equipment, and standard clinical monitors; observers, some technical staff and additional monitoring equipment were in the other half. This arrangement minimized the number of personnel and quantity of equipment in the immediate vicinity of the subject.

Additional cannulae for sampling arterial and venous blood were inserted in the non-dominant arm using local anaesthesia. Oxygen was administered by a single nasal cannula and a capnograph sampled airway gas from the contralateral nostril.

DRUG ADMINISTRATION

ORG 21465 was formulated in a buffered aqueous solution at a concentration of 20 mg ml^{-1}, pH 4. Each infusion of ORG 21465 was preceded by infusion of an equal volume of the buffered solution without ORG 21465 (inactive vehicle). After preparation, subjects rested quietly for a minimum of 20 min before administration of inactive vehicle, which took place close to 10:00. Another rest period of 10 min preceded infusion of ORG 21465. Both infusions were given into the dominant arm through the same cannula as the i.v. infusion over 60 s. Each subject received a single dose of ORG 21465 0.8, 1.0, 1.2, 1.5 or 1.8 mg kg^{-1}.

The first subject received 0.8 mg kg^{-1}, as this dose was predicted to be sub-anaesthetic in humans by extrapolation from animal data. Subsequent subjects received higher doses according to a dose escalation scheme, allowing consecutive subjects to receive larger doses until one subject became anaesthetized. When the first subject became anaesthetized, the next subject received the same dose; subsequently, dose increases were allowed provided that the previous subjects had been studied safely. Twenty-four hours after administration of the dose, biochemical and haematological data from each subject were reviewed before the next subject was studied.

MEASUREMENTS

Clinical observations

Clinical observations were made using two video cameras. One was located head high, at the foot of the bed, and monitored continuously the whole subject. A second, portable camera was used to document features of particular interest. All video images were time stamped. In addition, immediately after each subject was studied, an anaesthetist prepared a written summary of the subject's responses. Occurrence of the following observations were recorded and timed: pain on injection; loss of verbal contact; dropping a water-filled 20-ml syringe held between the thumb and forefinger of the supported dominant forearm, abducted approximately 30° from the supine subject; loss of eyelash reflex; and eye closure. During anaesthesia, at intervals of 30–60 s, subjects were called by their name and asked to open their eyes in order to determine their state of consciousness. Times to eye opening to direct verbal command, moving of limbs to direct command and recovery to a Ramsay sedation score[16] of 2 were noted. Evidence was sought of pain on injection, thrombophlebitis and any signs of excitation, including twitching, seizure, coughing, hyperreflexia or myoclonus.

Physiological measurements

Arterial pressure was measured directly until 90 min after administration of the dose when non-invasive methods were substituted and continued for 12 h. Heart rate was recorded for 12 h and cardiac index was estimated using bioimpedance (Bomed NCCOM 3) during the first hour after drug infusion.

Ventilatory frequency was monitored by nasal capnography. Adequacy of ventilation was judged empirically by the attending anaesthetist and supported by video recordings.

The EEG was recorded using a two-pair, five electrode system (Transmed TM-20). All electrode impedances were less than 10 kΩ.

Biochemical screening

Blood was obtained before the study and at 24 and 72 h after treatment. Concentrations of sodium, potassium, bicarbonate, urea, chloride, creatinine, total protein, albumin, bilirubin, creatinine phosphokinase, alanine transaminase, aspartate transaminase, gamma glutamyl transferase, alkaline phosphatase, glucose, calcium, phosphate, uric acid, cholesterol, triglycerides and acid glycoprotein were measured. Haemoglobin concentration, red blood cell variables, platelet count and differential white cell count were also measured.

Blood sampling and assay for ORG 21465

Arterial blood samples were obtained immediately before drug administration and at 0.5, 1, 2, 3, 4, 7, 10, 15, 20, 30, 45, 60, 120, 180 and 240 min after the start of drug infusion. An additional sample was obtained at the time of eye opening to command. When collecting samples, allowance was made for the cannula and three-way tap deadspace, estimated to be less than 0.2 ml, by withdrawing at least 0.5 ml before sampling. Samples (5 ml) were transferred to heparinized tubes, cooled and centrifuged within 1 h at 3000 rpm for 10 min. The separated serum was subsequently stored at −20 °C until analysis.

Extraction of ORG 21465 and internal standard (Org 1710, comparable with ORG 21465 but demethylated at the morpholinyl ring) from alkanized plasma was performed with n-hexane. Plasma concentrations of ORG 21465 were measured by capillary gas chromatography with mass-selective detection in the positive ion chemical ionization mode. Ammonia was used as the reactant gas. Capillary GC-MS was conducted on a Hewlett Packard 5890 series 11 gas chromatograph coupled directly to a Finnigan MAT SSQ mass spectrometer. The protonated molecular ion of ORG 21465 was monitored at m/z 446.1 and internal standard at m/z 404.1. Duplicate calibration samples (seven concentrations from 40 to 200 ng ml^{-1}), blank plasma samples and triplicate quality control (QC) samples of ORG 21465 in plasma at three concentrations (160, 400 and 1600 ng ml^{-1}) were included in every series of analyses. Per series of analyses, all samples of one or two subjects were measured. The inter-assay coefficient of variation (cv) was 11.2% at the low QC concentration. The intra-assay cv was 11.1% at the low QC concentration, 6.9% at the mid QC concentration and 4.7% at the high QC concentration. The accuracy of the assay, expressed as a deviation from the nominal spiked values (mean value/nominal value) of QC samples was 92.1% at the low QC concentration, 93.7% at the mid QC concentration and 99.9% at the high QC concentration. Results were mean values over nine analysis series. ORG 21465 is stable in human plasma for a period of at least 8 months. Repeated freezing and thawing does not influence ORG 21465 concentration.

PHARMACOKINETIC ANALYSIS

All pharmacokinetic analyses were performed using an iterative non-linear modelling program, NONMEM version IV,[17] on a Hewlett Packard series 9000/710 workstation. Mixed effects pharmacokinetic population models were fitted to the arterial drug concentration data. The mixed effects approach defines a single basic model of typical values (population means) for the pharmacokinetic variables. Variations in each individual from the basic model are defined by the use of a variable number of additional, user defined "inter-individual variability" parameters, each defining a degree of variability in one or more of the basic parameters. For example, clearance (*Cl*) was modelled as:

$$Cl=Cl_{typical}\times\exp(\eta)$$

where Cl=value for an individual, $Cl_{typical}$=typical value (mean) for the population, and η=normally distributed random variable with mean zero. Both the basic model and inter-individual variability can also be wholly or partially modelled as functions of physiological covariates, the aim being to reduce the residual degree of inter-individual variability. The basic variables of the models used here were volume of the central compartment (V_1), volume of the peripheral compartments (V_2 and V_3), clearance (Cl; elimination clearance=$V_1\times k_{10}$), fast distributional clearance ($\dot{Q}_1=V_1\times k_{12}$) and slow distributional clearance ($\dot{Q}_2=V_1\times k_{13}$). Volume of distribution at steady state (V^{ss}) is $V_1+V_2+V_3$. Population models were fitted using the first-order method of NONMEM with which the exponential error model illustrated earlier is equivalent to a constant coefficient of variability error model. Bayesian estimates of each individual's pharmacokinetic variables (for those where variability could be modelled) were then obtained using the *post hoc* step of NONMEM.

We first fitted individual two- and three-compartment models to the data from each individual. A three-compartment model was considered statistically justified if the −2 log likelihood (objective function) was more than 6 less then the reduced (two-compartment) model. The three-compartment model was justified in each case and therefore subsequent population base modelling was performed using a three-compartment model. We next built a population pharmacokinetic model, adding inter-individual variation parameters until no further modelled variation could be justified. The justification for each additional inter-individual variation parameters was for it to improve the goodness of fit statistic (−2 log likelihood) by >3.8 (evaluated against the chi-square distribution this is equivalent to significance at the 0.05 level), and to result in a visual improvement in the goodness of fit. Finally, using the same justification criteria we attempted to model each pharmacokinetic variable as a function of weight.

Results

We studied 10 male subjects, aged 22–34 yr, weighing 64–98 kg.

CHARACTERISTICS OF ANAESTHESIA

All subjects suffered discomfort on injection of both inactive vehicle and ORG 21465, with eight reporting pain. There were no cutaneous or cardiovascular signs of histamine release. The subject who received 0.8 mg kg^{-1} stopped speaking at 2.5 min but did not lose his eyelash reflex or drop the syringe. Anaesthesia was produced at all doses in excess of 0.8 mg kg^{-1} (table 1). The quality of induction was variable, with subjects who received 1.2 and 1.8 mg kg^{-1} displaying signs of airway irritation, notably coughing and sneezing. Induction of anaesthesia, as timed by syringe drop, took approximately 1 min

Table 1 Clinical responses to ORG 21465. Times from the start of drug infusion; all individual values are shown. In addition, mean values for each dose are shown in parantheses. N/A=Not available

	Dose (mg kg^{-1})

Recovery to Ramsay sedation score 2 (min)	N/A	(17.5) 15, 20	(17.33) 20, 20,12	(32.5) 35, 30.	(32.5) 30,35

and was clinically comparable with propofol and thiopentone. After a dose of 1.0 mg kg^{-1}, recovery to eye opening and moving limbs to command took 10 min. Higher doses produced a longer period of unconsciousness. The quality of recovery was good.

Excitatory phenomena were evident in all subjects and appeared to be dose related. Such phenomena ranged from increased muscle tone and shaking, at 0.8 mg kg^{-1}, to prolonged periods of violent coughing and sneezing, at 1.2 and 1.8 mg kg^{-1}, despite apparent anaesthesia. Airway reflexes were considered well preserved and apnoea was not observed.

ELECTROENCEPHALOGRAM

The EEG data were contaminated by large amounts of artefact caused by patient movement in response to questioning by the investigators and by excitatory movements so that it could only be evaluated crudely. The subject receiving the 0.8-mg kg^{-1} dose showed only increased alpha rhythm in association with sedation. Other subjects showed changes typical of anaesthesia with increased delta activity and a reduction in median EEG frequency to 2–3 Hz. No spikes, sharp waves or signs of cortical seizure activity were observed, however, the limited digitization rate and frequency response of the Transmed TM20 system implied that these phenomena may have been undetected.

PHYSIOLOGICAL MEASUREMENTS

During and immediately after infusion of drug, measurement of arterial pressure was compromised by the need for frequent blood sampling; this data set is therefore incomplete. Arterial pressure declined slightly with induction of anaesthesia (median decrease in systolic pressure was 13% at 4 min, largest individual decrease was 22% at 3 min). Heart rate increased immediately after the drug or inactive vehicle was infused (median increase 32% at 1 min, largest individual increase 58% at 1 min); this increase coincided with subjects experiencing pain during injection of inactive vehicle or drug. After loss of consciousness heart rate returned rapidly towards baseline levels but remained slightly elevated (median increase in heart rate 13% between 2 and 10 min). Changes in cardiac output were minimal. Two subjects required assistance to clear an obstructed airway. Apnoea did not occur and ventilation was judged adequate in all subjects. There were no significant biochemical or haematological abnormalities.

PHARMACOKINETICS

When subjects were modelled individually, three compartments (in contrast with two compartments) were justified, both visually and statistically in all cases. A typical subject is shown in figure 2. The model determined from the process of population model building was a three-compartment (non-weight-related) model with log normal inter-individual variation in clearance (*Cl*) and inter-compartmental clearance ($\dot{Q}$). A plot of all C_P values from all subjects against the value predicted by the typical population pharmacokinetic variables confirmed a lack of bias in the population model (fig. 3). Predictions were marginally improved when they were based on individual's pharmacokinetic variables calculated *post hoc*. The variability associated with the η series was quite small and consequently there was little difference between the prediction based on typical population values or individual values for pharmacokinetic variables (fig. 3) These *post hoc* η

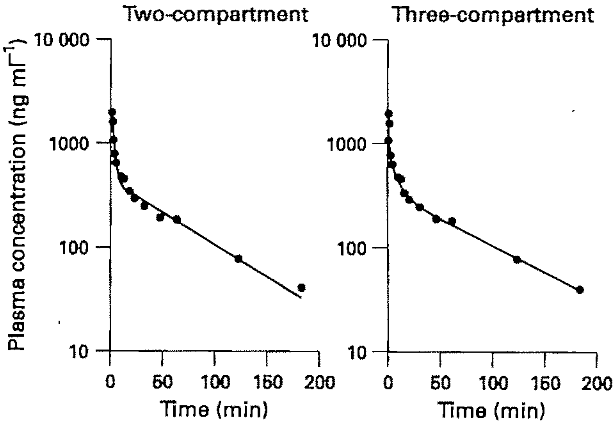

Figure 2 An example of data from a single subject fitted to two- and three-compartment models. Visually and statistically the three-compartment model is prefered.

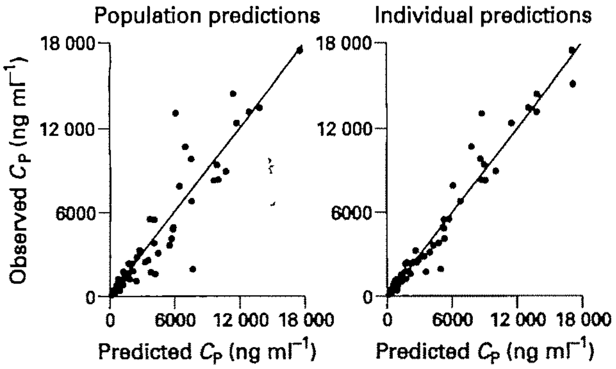

Figure 3 Predicted plasma concentrations (C_P) plotted against observed plasma concentrations based on typical population values and individual values.

Table 2 Typical population values (with variability) for the pharmacokinetic variables describing the time course of concentration of ORG 21465. *95% CI is a measure of the precision of the typical value. The true typical value has a 95% chance of falling within these limits. **CV is the residual unexplained variability; 95% of values will fall inside the typical value plus twice this value and the typical value minus twice this value. With NONMEM the variability is encoded into the structure of the model and if no value is present then there are insufficient data to fit such a variable and the variability cannot be determined

	Typical value	95% CI*	CV**
Clearance (litre min^{-1})	1.55	1.45–1.65	12%

values (the value by which the typical population pharmacokinetic variable must be adjusted to give an individual's value) were plotted against weight to confirm that there was no justification to model pharmacokinetic variables on a weight basis. There was no indication that the pharmacokinetic variables should be modelled as functions of weight; indeed when attempts were made to model with variables related to weight the overall prediction based on population PK typical values was clearly erroneous and the predicted *vs* observed values plot demonstrated systematic misfit. The values and variability of the variables determined for this model are shown in table 2.

Discussion

An ideal i.v. anaesthetic would provide smooth induction of anaesthesia, haemodynamic stability and rapid recovery without accumulation after prolonged administration. It would also be water soluble, free from histamine release or adrenocortical suppression, and unsupportive of bacterial growth. A high therapeutic index would be advantageous. The current i.v. anaesthetic agents propofol, thiopentone and etomidate offer these characteristics to varying degrees, although none is water soluble. Anaesthetic steroids have modest haemodynamic effects and are removed rapidly from the body by hepatic metabolism and elimination; they also have high therapeutic indices.[14] It is these characteristics which have encouraged further development of anaesthetic steroids. Preclinical evaluation of ORG 21465 suggested that it had the characteristics of an excellent i.v. anaesthetic[15] and its progress from laboratory studies to humans was logical.

Although we injected ORG 21465 as an aqueous solution, all subjects reported pain on injection of both the inactive vehicle (water and buffers) and ORG 21465 itself, suggesting that the formulation may need adjustment.

We have confirmed that ORG 21465 is an anaesthetic for humans with onset of anaesthesia within 45–60 s of the start of injection according to dose and choice of end-point for induction. Similar induction times are seen with other agents. Assessment of induction times in this study was complicated by the different rates of drug administration to our individual subjects; studies with other agents have demonstrated that induction times of i.v. anaesthetic agents are dependent on the rate at which they are infused.[11 18] All subjects received the drug over 1 min; this fixed period was chosen to facilitate pharmacokinetic analysis while being clinically realistic. In all animal studies of ORG 21465 the drug was injected over 10 s.[15]

Our investigation was not a formal dose-finding study, however, our data suggest that when ORG 21465 is infused into humans over 1 min, the induction dose is approximately 1 mg kg^{-1}. Recovery from anaesthesia was slower than might be expected with induction doses of thiopentone or propofol, with some subjects requiring 35 min to return to a Ramsay score of 2.

The haemodynamic data collected in this study were limited by frequent sampling of arterial blood. We did not observe gross changes in arterial pressure but it would be premature to assume that anaesthesia with ORG 21465 is haemodynamically stable.

The main side effect of ORG 21465 was excitation with movements, which affected all parts of the body. A wide range of excitatory effects have been associated with i.v. anaesthetic agents, most notably with etomidate and methohexitone but also with propofol, eltanolone, midazolam and thiopentone.[6 19] Our EEG data were limited and this reflects the basic apparatus and need to intermittently stimulate the subjects to assess hypnosis. More accurate EEG recording requires more electrodes, better equipment and an unstimulated subject; reliable detection of spikes and sharp waves in the EEG requires a high digitization rate. Nevertheless, we saw no evidence of cortical excitation. Although technical limitations imply that some spikes might have been undetected by our apparatus, it is probable that the excitation caused by ORG 21465 is of sub-cortical origin. This can only be confirmed by additional studies with more advanced EEG recording.

We have demonstrated that ORG 21465 was an effective i.v. anaesthetic in humans and shared some of the properties of other anaesthetic steroids. It would therefore seem an agent worth further study. Particular attention should be paid to its EEG effects and recovery characteristics.

Summary

ORG 21465 has been found to possess anaesthetic properties in humans and its pharmacokinetics are known. We performed this study to confirm the characteristics associated with its administration and to define its pharmacodynamic profile, in particular to explore the relationship between sedation, anaesthesia, excitation and plasma drug concentrations. A water soluble preparation of ORG 21465 was administered to six male volunteers as a series of three 15-min computer-controlled, pharmacokinetic model-driven infusions targeting three exponentially increasing plasma concentrations: 0.5, 1 and 2 $\mu g\ ml^{-1}$. The clinical characteristics of the resultant sedation and anaesthesia were observed. Plasma concentrations of ORG 21465 were measured during and for 500 min after the infusions and the EEG recorded. A sigmoid e-max effect compartment pharmacodynamic model was fitted to the plasma concentrations and an EEG derivative (spectral edge frequency (SEF)). Anaesthesia with ORG 21465 was associated with involuntary movements in all subjects. A steady state concentration of 1180 ng ml^{-1} depressed SEF by 50%, the Hill factor describing the sigmoid nature of the concentration–response curve was 1.42 and the equilibration rate constant of the biophase was 0.112 min^{-1}. Anaesthesia with ORG 21465 was found to be unsatisfactory because of involuntary movements and slow equilibration with the biophase. (*Br. J. Anaesth.* 1997; **79**: 433–439).

Key words
Anaesthetics i.v., steroid. Pharmacology, ORG 21465. Sedation. Pharmacodynamics.

ORG 21465 is a water soluble preparation of (2β, 3α, 5α)-3-hydroxy-2-(2,2 dimethylmorpholin 4-yl) pregnane-11,20-dione. In preclinical testing in mice, rats, dogs and monkeys, ORG 21465 appeared safe and potentially suitable as an i.v. anaesthetic in humans.[1] Infusion into 10 human volunteers of ORG 21465 0.8–1.8 mg kg^{-1} over 1 min induced sedation or anaesthesia without histamine release. Excitatory phenomena were observed in all subjects and were dose related; no spikes were seen on the EEG.[2] This previous study also established the pharmacokinetics of ORG 21465 in humans.

We report an open study evaluating the pharmacodynamics of ORG 21465. A computer-controlled drug infusion was used to maximize the experimental return from a small number of subjects. Spectral edge frequency was used to quantify the CNS effect of the agent.

Subjects and methods

SCREENING AND PREPARATION OF SUBJECTS

Six healthy male volunteers who had previously received a bolus of ORG 21465 returned for a second administration. The screening procedure is described in our accompanying article.[2] All subjects gave informed written consent and the study was approved by the local Ethics Committee. Consecutive subjects were studied at intervals of at least 24 h, allowing time to evaluate analysis of follow-up blood samples obtained 24 h after administration of the dose from the previous subject but one.

Subjects were admitted to hospital the night before drug administration and underwent a physical examination and urine screening for drug abuse or alcohol (Merck Triage kit). Subjects were fasted from 22:00 and permitted to drink water until midnight. At 06:00 Hartmann's solution was infused at a rate of 3 ml kg^{-1} h^{-1} into the non-dominant forearm. One hour before the drug infusion, a cannula was placed in the non-dominant radial artery and a long venous catheter (Abbot Ireland Ltd) was advanced from the antecubital fossa of the

dominant forearm into the thorax to provide central venous access for drug administration. Oxygen was administered by a single nasal cannula and a capnograph sampled airway gas from the contralateral nostril.

DRUG ADMINISTRATION

ORG 21465 was formulated in a buffered aqueous solution at a concentration of 10 mg ml^{-1}. After preparation subjects rested for a minimum of 20 min before administration of ORG 21465 which commenced close to 10:00. Each subject received ORG 21465 as a computer-controlled infusion over 45 min, aiming to achieve stable arterial plasma concentrations of 0.5, 1 and 2 mg ml^{-1} for three consecutive periods of 15 min. This was administered from a Harvard 22 electronic syringe pump controlled by an Elonex 386 personal computer running the pharmacokinetic modelling and drug infusion software STANPUMP (version June 13, 1995).(STANPUMP is freely available from the author, Steven L. Shafer, MD, Anesthesiology Service (112A) PAVAMC, 3801 Miranda Avenue, Palo Alto, CA 94304, USA and on the World Wide Web at http://pkpd.icon.palo-alto.va.gov.) The three-compartment pharmacokinetic model used to control the pump was determined during interim modelling (developed in the course of the previous study which included these six volunteers) and made the assumption that the variables of the model would be related to weight. It had the following variables: V_1 0.246 litre kg^{-1}, k_{10} 0.074667 min^{-1}, k_{12} 0.062 min^{-1}, k_{13} 0.27333 min^{-1}, k_{21} 0.0056167 min^{-1} and k_{31} 0.077167 min^{-1}, where V_1=central volume of distribution and k_{xy} are inter-compartmental rate constants.

The drug delivery system was tested to confirm performance using an Ultramedic SDA 1 computerized syringe tester (Ultramedic Ltd, Wavertree, Liverpool L13 1EJ). Dynamic performance of the entire system was tested over two complete runs of the three-step infusion. Actual performance of the drug infusion system during the clinical study was confirmed by weighing.

MEASUREMENTS

Clinical observations and measurement of physiological variables mirrored the previous study and have been described in detail elsewhere.[2] Briefly, the behaviour of the subjects was recorded using video cameras, arterial pressure was monitored invasively and cardiac output non-invasively. Times to cessation of speech, eye closure, loss of eyelash reflex and return of eye opening and limb movement to command, and recovery to a Ramsay sedation score[3] of 2 were recorded. Excitation was quantified by a single observer who reviewed all video tapes in a single 2-day period. Using a custom-written computer program synchronized with the video timing signals, every individual excitatory movement was identified and graded on an arbitrary 10-point scale where minor movements only visible on close-up (e.g. tremor of a digit or slight facial twitching) scored between 1 and 3; larger movements ranging from myoclonus to major spasms of the whole body scored between 4 and 10. A movement score was calculated for epochs of 1 min duration by summing the excitation scores of each excitatory event during that particular epoch. Thus five myoclonic jerks each scored as 6 on the arbitrary scale would give a movement score for that minute of 30.

Blood sampling and assay for ORG 21465

Venous blood was obtained before the study and at 24 and 72 h for measurement of a wide range of biochemical and haematological variables.

Arterial blood samples were obtained immediately before drug administration, at 5-min intervals during infusion and at 5, 10, 15, 20, 25, 30, 40 and 50 min and 1, 1.25, 1.5, 1.75, 2, 2.25, 2,75, 3, 3.5, 4, 4.5, 5, 6, 7, 8, 9 and 10 h after infusion. The 15-, 30- and 45-min samples during infusion of the drug were obtained immediately before the change of infusion rate. Samples (5 ml) were transferred to heparinized tubes, cooled and centrifuged within 1 h at 3000 rpm for 10 min. The separated serum was subsequently stored at −20 °C until analysis.

Concentrations of ORG 21465 in serum were measured with a capillary gas chromatographic assay with mass-selective detection (GC-MS) after n-hexane extraction. Details of the analytical method and its accuracy have been reported in our previous study.[2]

Electroencephalogram (EEG) recording

The EEG was recorded from seven positions overlying cortical motor and sensory areas. Electrodes were silver–silver chloride cups filled with conducting paste and mounted with collodion. Expressed in 10-20 system co-ordinates, which is the standard in EEG montage, the positions were at F3, Fz, F4, C3, C4, P3 and P4. A common reference electrode was used at position Cz. All electrode impedances were less than 5 kΩ. The wires from the electrodes to the pre-amplifiers were short and shielded for optimal signal-to-noise ratio. The pre-amplifiers were fitted in a small battery powered unit connected to the main amplifier unit by an optical link.[4] The amplified analogue signals were filtered (0.3–200 Hz), digitized at 1000 Hz with 12 bits (1:4096) precision and stored on opto-magnetic computer media. Synchrony between the TCI system and the EEG recorder was maintained by time markers stored with the EEG signals.

Analogue data were also led to a video processor that constructs constantly scrolling EEG traces on the left half of a video screen together with the images of one of the cameras on the right half of the screen. The combined images of EEG traces and camera were stored on VHS video tape.

The EEG was inspected visually for artefacts. Eye blinks give rise to characteristic, moderate amplitude waveforms in the EEG, facial and neck muscle activity gives high frequency components and gross movements give baseline shifts with very low frequencies. After visual inspection of all EEG data as consecutive 5-s epochs, artefacts were marked and excluded automatically from further analysis. Spectral edge frequency (SEF) was calculated as follows: each accepted epoch was transformed to a power spectral density curve by Fourier transformation followed by power conversion (the modulus of the square of the complex values). For each spectrum the power present in the frequency band of 0.6–48 Hz was calculated and normalized to 100%. SEF was determined such that the power present in the band between 0.6 Hz and this SEF was equal to 95%.

Electromyogram (EMG) recording

In the final subject two electrodes were placed 6 cm apart in the pectoralis major at a position where previous subjects showed pronounced muscle activity. The differential signal was band-filtered (100–300 Hz) and the envelope (rectification, followed by low pass filtering) of this signal was stored as an additional channel with the EEG. The onset of EMG bursts were marked with time markers and 1-s segments of the EEG centred on the marker were extracted. All selected segments were averaged.

PHARMACOKINETIC AND PHARMACODYNAMIC ANALYSIS

Our accompanying article describes the estimation of the pharmacokinetic parameters of ORG 21465.[2] The purpose of the studies presented here was to estimate the parameters of a pharmacodynamic model. To achieve this our only prerequisite was to describe the observed plasma concentration profile well in each individual; the actual pharmacokinetic model used was unimportant. All modelling was performed using NONMEM Version IV level 2.1 (University of California).[5]

For the purpose of the current analysis a population pharmacokinetic model was fitted to the plasma concentrations obtained during and after the target-controlled infusions (six subjects) and the data from the previous bolus dose study (10 subjects). No attempt was made to build the population model, but rather the structure of the population model determined during the previous analysis was used with one additional parameter. Because the formulation of the drug and its method of administration differed during the infusion compared with the bolus study we allowed the bioavailability to vary between these two administrations. We then obtained Bayesian estimates of each individual's pharmacokinetic variables using the *post hoc* step of NONMEM. This approach permitted us to estimate afresh the pharmacokinetic variables after administration of a larger dose of drug compared with previously and also to describe well the observed plasma concentrations. Each individual's pharmacokinetic parameters were then incorporated into NONMEM's input to enable the development of a population pharmacodynamic model.

A pharmacodynamic model was fitted to the SEF data from each individual. SEF values at 1-min intervals during the target-controlled infusions and for 45 min after drug administration was discontinued were included in the data set. All SEF values were referenced to the value immediately before drug administration which was considered as unity. Effect was modelled to follow a sigmoid relationship to a maximum value of 100% as anaesthetic concentration in a hybrid effect compartment increased. The slope of the concentration–effect relationship was defined by the variable gamma (γ) and the concentration giving 50% reduction in the SEF as C_{50}. The effect compartment was of minimal volume but with its own rate constant (k_{e0}). We also modelled an increase in SEF which multiplied the value that it otherwise would assume (beta activation factor). This effect was modelled as occurring when any anaesthetic was present in the system.

We next built a mixed effects pharmacodynamic model. The mixed effects approach defines a single basic model of typical values (population means) for the pharmacodynamic parameters; variations in each individual from the basic model are defined by the use of a variable number of additional, user-defined "inter-individual variability" parameters each defining a degree of variability in one or more of the basic variables. For example, C_{50} was modelled as:

$$C_{50}=C_{50\text{typical}}\times\exp(\eta)$$

where C_{50}=value for an individual, $C_{50\text{typical}}$=typical value for the population, and η=a normally distributed random variable with mean zero. We added inter-individual variation parameters until no further modelled variation could be justified. The justification for each additional inter-individual variation parameter was for it to improve the goodness of fit statistic (−2 log likelihood) by >3.8 (evaluated against the chi-square distribution this is equivalent to significance at the 0.05 level) and to result in a visual improvement in the goodness of fit.

Results

We studied six male subjects, aged 22–30 yr, weighing 63–82 kg. The performance of the infusion system was satisfactory during bench testing. Measured errors during steady infusion at 10, 100 and 1000 ml h^{-1} were −0.53%, −0.91% and −0.6%, respectively. During dynamic testing over two complete runs of the three-step drug infusion with the pump driven by the STANPUMP software, the greatest measured error was 2.4% at 5 min which decreased progressively to 1.08% at 15 min and to 0.75% at 45 min. Weighing of the infusion syringes used during the study confirmed that the correct volume of drug had been infused.

CHARACTERISTICS OF ANAESTHESIA

None of the subjects reported discomfort during central venous injection of ORG 21465. There were no cutaneous or cardiovascular signs of histamine release. All subjects were sedated at the lowest target concentration infusion (0–15 min, target plasma concentration of 0.5 mg ml^{-1}). Five subjects became anaesthetized during the second stage of the infusion

Table 1 Clinical responses to ORG 21465; all values are time (min) after drug administration

	Subject No.							
	1	2	3	4	5	6	Mean	SD

Recover to Ramsay score 2	34	30	40	20	40	30	32.3	6.9

(15–30 min, target plasma concentration of 1 mg ml^{-1}) with loss of verbal contact and loss of eyelash reflex. The remaining subject became anaesthetized during the third stage of the infusion (30–45 min, target plasma concentration of 2 mg ml^{-1}). Times to loss of verbal contact and eyelash reflex were variable (table 1) and recovery from anaesthesia was slow (table 2). No subject moved in response to verbal command within 10 min of the end of drug infusion.

Systolic and diastolic pressures declined slightly with anaesthesia (fig. 1). Heart rate increased progressively between 30 and 45 min which coincided with the peak period of excitation. Some respiratory depression was evident in three subjects, of whom one became apnoeic and required assisted ventilation.

Excitatory phenomena were evident in all subjects and appeared to be dose related. Such phenomena ranged from increased muscle tone and twitching to extreme coughing and sneezing. Typically, excitation commenced with twitching of the fingers and developed into movements of the upper limbs and torso. In most subjects, hypertonia of the lower limbs was noted with extension at the knees, ankles and toes. There was no hyperreflexia and the plantar response remained down-going. In two subjects, a few beats of ankle clonus were elicited at the peak of excitation. Minor stimuli resulted in marked withdrawal of the limb. Excitation occurred before loss of consciousness and continued into the recovery phase; two subjects described feeling twitchy after recovery from anaesthesia. Movement scores were determined for five subjects (fig. 2). In the remaining subject, excitation was mainly coughing and sneezing and appeared qualitatively different from the other five subjects. For this reason no attempt was made to quantify this subject's excitation. All subjects reported favourably on their experiences.

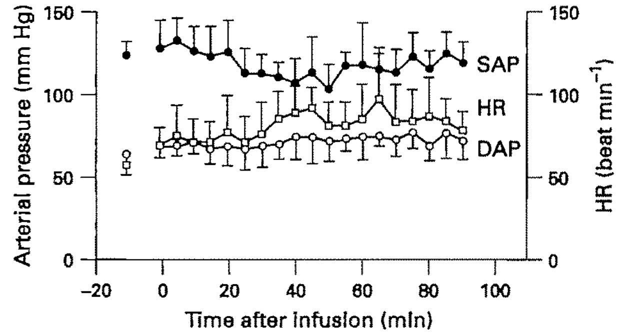

Figure 1 Systolic (SAP) and diastolic (DAP) arterial pressures and heart rate (HR) before, during and after a three-stage 45 min infusion of ORG 21465. Times are from the start of infusion. Baseline measurements recorded before instrumentation and cannulation are shown for comparison.

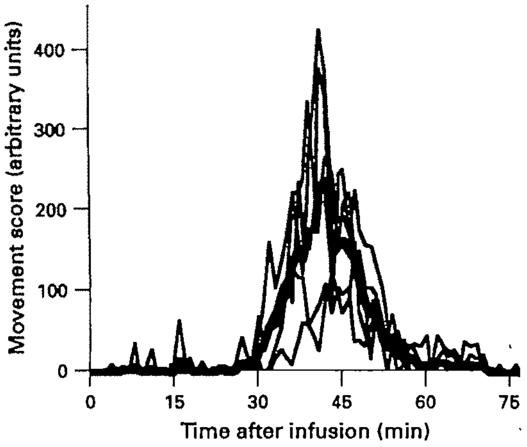

Figure 2 Movement scores for five subjects. All excitatory movements were graded by severity on an arbitrary 10-point scale. The movement score is the sum of individual scores of all movements occurring within a 1-min period. Scores for individual subjects are shown as thin lines; bold line=group average.

EEG

EEG recordings showed changes typical of anaesthesia: a gradual increase in amplitude and shift from desynchronized fast activity towards synchronized slow activity. Except for a few spikes with moderately fast rise times and waves with moderately sharp aspects, no consistent signs of epileptic activity were observed. These sharp waves did not coincide with involuntary movements. During involuntary movements no abnormal patterns were observed in the EEG.

Typical drug effects in the EEG were: theta activity 3 min after the start of infusion, preceded or followed by an increase in alpha activity, then slow delta waves at 4–10 min. Initially, these delta waves were accompanied by faster activity, beta activation, which remained present during the second infusion period and disappeared with the third infusion. The third infusion was associated with increased delta amplitude leading to periods of burst suppression. Recovery after drug withdrawal started with reappearance of high frequency components. Next the delta activity accelerated and was gradually replaced by theta, alpha and occasionally beta activity.

The EEG data were summarized quantitatively in the SEF. Before drug administration, the SEF fluctuated at around 15 Hz with wide individual variation. During the first infusion SEF increased abruptly and reached a maximum value of 25 Hz, thereafter decreasing monotonically and, by the end of the first infusion period, SEF values (typically) approximated pre-drug values. After the start of the second infusion period, the SEF decreased monotonically in all subjects to, typically, 10 Hz. The start of the third infusion caused a further rapid decrease in SEF to, typically, 5 Hz. After the end of drug delivery, SEF values increased immediately and monotonically, reaching pre-drug values at, typically, 90 min.

EMG

In the single subject studied, trains of EMG bursts occurred periodically, with a mean interval of 380 ms between bursts, and a median of 3 bursts per train. A total of 777 bursts in 245 trains were observed. The trains of EMG bursts coincided with visible activity of the muscle on the synchronized video recordings. To avoid confusing a cortical somatosensory response to the bursts with a true cortical origin, only the first EMG burst of each train was included in the averaging procedure. The result of the averaging process of the EEG and the EMG traces triggered by the onset of bursts is shown in figure 3. No significant deflections of the averaged EEG were observed before the start of the first EMG burst of each train.

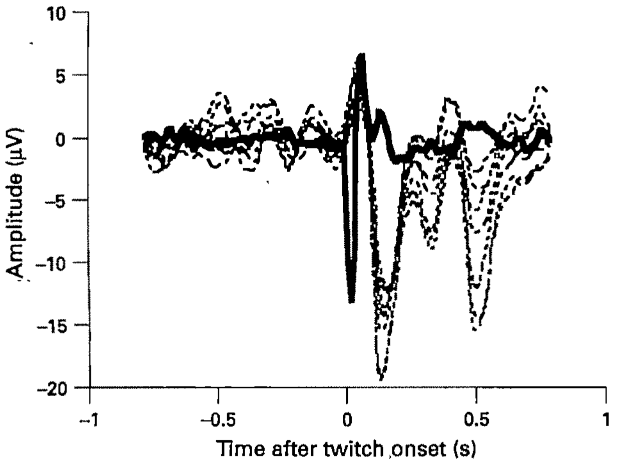

Figure 3 EEG (seven channels; thin lines) and EMG (one channel; bold line) averages triggered on the onsets of the first burst of EMG trains (n=245).

Table 3 Typical population values (with variability) for the pharmacokinetic variables describing the time course of concentration of ORG 21465. Model fitted to data from both the previous bolus dose study and the target-controlled infusion study. *95% CI is a measure of the precision of the typical value. The true typical value has a 95% chance of falling within these limits. **CV is the residual unexplained variability, 95% of values will fall inside the typical value plus twice this value and the typical value minus twice this value. With NONMEM the variability is encoded into the structure of the model and if no value is present then there are insufficient data to fit such a variable and the variability cannot be determined

	Typical value	95% CI*	CV**

C_{50}(depression) (ng ml^{-1})	1180	974–1386	26%
γ	1.42	1.32–1.51	
Beta activation factor	1.44	1.20–1.67	0.32

PHARMACOKINETICS

We used the structure of the pharmacokinetic model determined using data from the bolus study (i.e. a three-compartment (non-weight-related) model with log normal inter-individual variation in clearance (Cl) and inter-compartmental clearance ($\dot{Q}$)). We also allowed bioavailability to vary from the bolus to the infusion encounter because the drug was formulated differently and given by a different route. The variables of this model fitted to data from both bolus (10 subjects) and infusion (six subjects) studies are given in table 3. The model gave a good description of the observed plasma concentrations in all subjects.

A population pharmacodynamic model with inter-individual variation in C_{50} and in the beta activation factor was supported by the data (table 4). No additional inter-individual variation could be determined. In all individuals it fitted well the observed SEF values.

Discussion

The aim of this study was to determine the clinical characteristics of anaesthesia with ORG 21465 in humans. We also wished to elucidate further the time course of anaesthesia and how this time course can be related to the concentration of the drug in plasma. We chose a sophisticated study design with computer-controlled drug infusion and multiple end-points. Drug development is expensive and time consuming and not without risk to the volunteer subjects. Investigators therefore have a responsibility to obtain the most information from each human exposure. Our design allowed us to maximize the information yield while remaining within the dose supported by animal administrations and limiting anaesthesia and recovery time. As expected, ORG 21465 induced anaesthesia in all of our subjects with minimal effects on cardiovascular variables. As before, the drug caused dose-related involuntary movements (excitation) to some degree in all subjects. We were also able to demonstrate that the effect of the drug on the SEF could be modelled assuming a simple sigmoid concentration–response relationship and that the site of action of the drug (biophase) equilibrated slowly with the concentration of drug in plasma.

One of the main purposes of this study was the determination of the pharmacodynamic characteristics. To do this we chose to administer target-controlled infusions at three different target concentrations. This is a departure from the "usual" method used to determine the equilibration rate of a drug with its biophase, that is infusing a drug at a relatively slow rate until almost maximum effect is observed, then discontinuing the drug. During and after this administration, drug concentration and effect are measured and effect is plotted against drug concentration. The rate of equilibration is calculated to explain the hysteresis between the onset and offset curves. We devised our method because we were uncertain how much drug would be required to give nearly maximum effect, and (given the paucity of data for this drug in humans) we were severely constrained in the total quantity of drug that we could give to each volunteer. The method that we used aimed to produce an early constant quantity in plasma and then calculate a rate constant directly from the resultant time course of effect. Using this method we were able to determine exactly how much drug would be given in advance and thereby give the maximum permissible to each volunteer and maximize the quantity of information obtained. We also hoped that the three infusion targets would approach a stable effect on each occasion and would thus give three points on the concentration–effect curve. This design gave us a large amount of information which could be confidently modelled but we are left with some reservations.

To produce an early constant concentration in plasma required that the model used to drive the infusions was correct and predictive. In part because of time constraints, we chose a model with its variables related to weight; this proved not to be a very predictive model. Later we chose a much more predictive pharmacokinetic model; this discrepancy is of no consequence as the doses given were known. However, because the model used to determine dosing was not closely predictive, the plasma concentrations during the target-controlled infusions were not constant, particularly early in each infusion. A second reservation was that SEF continued to change at the end of each infusion target. Thus steady state was not approached and our ability to determine three points on the concentration–effect curve was compromised. However, the iterative modelling process we used to determine the pharmacodynamic model is insensitive to both these limitations and we were not prevented from confidently determining the pharmacodynamic variables.

We included a beta activation factor in the pharmacodynamic model because this improved the model and is intuitively sensible. EEG activation during sedation is well recognized[6] and the spectral edge seldom has a true monotonic relationship with drug concentration unless induction of anaesthesia is very rapid when activation becomes short or even absent. In our subjects, sedation (time to speech cessation) lasted 15–31 min and EEG activation was obvious.

We found that ORG 21465 equilibrated slowly with the biophase with a k_{eo} value of 0.112 min^{-1}. The time required for the biophase concentration to reach 50% of the plasma concentration ($T_{1/2}\ k_{eo}$) can be calculated as $0.693/T_{1/2}\ k_{eo}$ which for ORG 21465 is 6.19 min. This is comparable with that reported for eltanolone (6.9 min)[7] but much slower than thiopentone (0.58 min).[8] Anaesthetists value drugs which "act quickly" and biophase equilibration is an important determinant of onset (and offset) of drug action. For a new i.v. anaesthetic to be successful, whether water soluble or not, it would need rapid biophase equilibration. This factor may in part explain the failure of eltanolone and gives a clear target for other candidate i.v. agents. The physicochemical determinants of $T_{1/2}\ k_{eo}$ are currently unclear. Water solubility alone cannot be the only factor as the water soluble opioids alfentanil and remifentanil equilibrate rapidly ($T_{1/2}\ k_{eo}$ 0.96 and 1.6 min, respectively).[9]

The degree of excitation observed during this study was greater than that seen with any currently used i.v. anaesthetic agent, including methohexitone and etomidate. The excitation seen was clinically unacceptable and its appearance during light sedation with persistence through light and deep anaesthesia into recovery eliminates any possibility that it might be avoided by judicious dosing or restricting the agent to sedation. Our attempt to quantify excitation using an arbitrary 10-point scale has its limitations; nevertheless, the use of a single assessor reviewing all the videotapes consecutively made the process as objective as possible. It is clear from figure 2 that excitation was greatest at higher plasma concentrations of ORG 21465. The scale of excitation ranged from minimal to severe and it is of interest that subjects who experienced the most excitation during the bolus study were also the most affected during the infusion study. These clinical characteristics are similar to anaesthesia with other steroids[10] and will certainly prevent the use of this drug as an anaesthetic in humans. The relationship between the EEG and this excitation deserves some exploration. The EEG contained components that were cortical in nature and related to involuntary movements. Inspection shows that these cortical components followed (rather than preceded) both movement and EMG changes in temporal sequence. This strongly supports the hypothesis that cortical activity is not involved in generating this muscle activity. Because of the lack of cortical activity the involuntary movements are best described as extrapyramidal.

There appeared to be three major problems with ORG 21465. First, pain on injection, which we observed during our previous study (using an aqueous solution of pH 4 administered into a peripheral vein). Pain on injection was not observed during this study because of central venous administration. This permitted the study of a sedative dose of ORG 21465 without modification of its effects by pain. Central venous administration is not a routine route for induction of anaesthesia and were the drug to be developed further, alternative formulations might be investigated. A second major problem was excitation of a degree that is not clinically acceptable to practising anaesthetists and which appeared in all subjects. The final problem was slow equilibration of the drug with the biophase which results in slow induction of anaesthesia, difficulty in titrating dose to effect and slow recovery.

We have demonstrated that this steroidal anaesthetic can induce and maintain anaesthesia with modest haemodynamic changes similar to those seen with other anaesthetic steroids. However, ORG 21465 is not a useful anaesthetic agent for humans.

Prognosis of intraoperative brachial plexus injury: a review of 22 cases

B. BEN-DAVID AND S. STAHL

Summary

A retrospective review over 6 yr of patients presenting to the hand clinic was performed to identify cases of postoperative brachial plexopathy (PBP) and to assess both prognosis and early indices of prognosis. Over this period (1989–1995), 22 patients were referred by the hospital's surgical departments to the hand clinic because of PBP. Eight cases followed open heart surgery (OHS) and 14 followed non-cardiac surgery (NCS). Median full recovery took 10 (range 4–16) weeks and 20 (8–50) weeks, respectively. Long-term follow-up revealed one OHS patient with residual tingling and three NCS patients with residual weakness. Brachial plexopathy after median sternotomy was characterized by a predominance of sensory complaint in the lower roots of the plexus. Injury after non-cardiac surgery was reflected by a predominance of motor deficit in the upper and middle roots. Brachial plexus injury after cardiac surgery carries an excellent prognosis for full functional recovery. Although the limited number of cases precludes statistical substantiation, the data suggest that the prognosis of PBP after non-cardiac surgery may be worse in males, diabetics, those with injury to all roots of the plexus and, when in addition to the motor deficit there is sensory loss and pain or dysaesthesia. At a 1 week "prognostic milestone", 79% of NCS patients with significant symptomatology enjoyed complete recovery although this took as long as 5 months to 1 yr in 50% of patients. At a 6–8 week "prognostic milestone", 50% of those who had not yet had improvement in the motor deficit suffered residual neurological deficit. All patients recovered to a significant extent even when recovery was not complete and none suffered from late deterioration or chronic pain. (*Br. J. Anaesth.* 1997; **79**: 440–445).

Key words
Complications, brachial plexus injury. Nerve, damage (postoperative).

Postoperative brachial plexopathy (PBP) has been documented in the literature for more than 100 yr. PBP is generally believed to be a result of traction injury of the nerves with compression a contributing factor.[1] Both stretching and compression of the nerve ultimately lead to ischaemia of the vasa nervorum and subsequent injury to the nerve.[2–4] In addition, there may be rupture of intraneural capillaries and haematoma formation with further compression.[1] Several factors have been associated with intraoperative brachial plexus injury, including concomitant patient disease, anatomical variations, positioning of the patient, surgical factors and physiological factors (table 1).

The prevalence of PBP has been estimated at 0.02–0.06%.[1,5,6] A recent review of 1541 closed anaesthesia malpractice claims included 227 (15%) for nerve injury. Of these, brachial plexus injury represented 23% and was second only to ulnar neuropathy (34%) in frequency.[7] Insofar as these cases draw from insurance claim files, they almost certainly represent cases of residual loss and dysfunction. Yet previous authors have suggested that the long-term outcome in cases of intraoperative brachial plexus injury is almost invariably good—an apparent contradiction.[1,8–10] Review of the literature regarding prognosis and outcome of PBP reveals a relatively sparse published data base.[1,6,10,11] This is particularly true if one considers separately those cases occurring after non-cardiac surgery.

It is reasonable to assume that an awareness of the potential for brachial plexus and other nerve injuries together with a knowledge of the pertinent anatomy, pathogenesis and associated risk factors should reduce the incidence of these injuries. However, this information is of little practical value when confronted with such a patient after operation. Foremost among the patient's anxious questions will be with regard to prognosis. This retrospective review was undertaken in order to specifically address the question of prognosis of PBP.

Patients and methods

The records of the Rambam Medical Center Hand Clinic were searched for all cases of intraoperative brachial plexus injury occurring during the period 1989–1995. Both clinic and inpatient hospital charts were reviewed thoroughly and the patients, where possible, were contacted for long-term follow-up.

All patients included in this review were those who presented after operation to the hand clinic following surgery at this institution. The data do not include

Table 1 Factors associated with intraoperative brachial plexus injury

- Concomitant disease
  - Diabetes mellitus
  - Hypothyroidsim
  - Pernicious anaemia
  - Alcoholism
  - Pre-existing neuropathy
  - Herpes zoster
  - Polyarteritis nodosa
  - Peripheral vascular disease
  - Coagulopathy
- Concomitant anatomical predisposition
  - Cervical rib
  - Scalene muscle hypertrophy
  - Deformity (e.g. post-traumatic) of shoulder region
  - Anomalous derivation of plexus
- Positioning
  - Steep Trendelenburg
  - Steep Trendelenburg+shoulder braces
  - Steep Trendelenburg+wrist suspension
  - Excessive abduction of arm (>90°)
  - Dorsal extension at shoulder
  - Posterior shoulder displacement
  - External rotation of arm
  - Excessive rotation of head
- Surgical
  - Prolonged operative time
  - Median sternotomy
- Physiological
  - Hypothermia
  - Hypotension

those patients who had in-hospital consultations unless the patient went on to receive care through the outpatient hand clinic. No patient presented to the clinic sooner than 1 week after operation. Patients were seen at monthly intervals for 2–3 months after achieving maximum recovery. Long-term follow-up to verify residual injuries and to eliminate the possibility of late deterioration was provided by phone contact during the gathering of data for this review.

Evaluation of all patients included a detailed history covering concomitant diseases and predisposing factors, a clinical history regarding upper extremity pain, paraesthesia, numbness and weakness, and physical examination of all motor and sensory functions supplied by the brachial plexus. Each patient's injury was described by a specific description of the involved nerve roots and by a description of the initial presentation in terms of pain, motor and sensory impairment. For the purposes of this review these disturbances were classified on three-point scales. These scales were: motor: 1=paralysis, 2=paresis, 3=no weakness; sensory: 1=anaesthesia, 2=hypoaesthesia, 3=normal sensation; and pain: 1=frank pain, 2=dysaesthesia, 3=no pain. Electromyography (EMG) was not performed in the early postoperative period as this would only be indicated to validate suspicion of a pre-existing neurological condition.[12] Electrophysiological studies were performed 6–8 weeks after operation, but only in those patients who had yet to demonstrate significant clinical improvement. The purpose of the study was to establish nerve continuity and to serve as a baseline for further evaluation and decision making regarding other intervention (e.g. surgical neurolysis).

All patients were treated in a similar manner. To prevent contractures, occupational therapy was undertaken for splinting of the wrist and fingers where indicated. Weakness resulting in shoulder subluxation or difficulty in elbow flexion was treated with a supportive sling. Active and passive physical therapy was conducted agressively in all patients. Particular attention was paid to full passive range of motion exercises several times a day to maintain joint motion and prevent contractures.

Results

A total of 22 cases of PBP were identified; 14 of these had undergone non-cardiac surgery (NCS) (table 2) and eight had undergone open heart surgery (OHS) with median sternotomy (table 3). In the NCS group there were six women and eight men, with mean ages of 52 and 57 yr, respectively. In the OHS group there were seven males (mean age 62 yr) and one female (aged 45 yr). Both groups had patients with possible contributing factors. Hospital inpatient chart reviews revealed that all patients had undergone general anaesthesia, but none of the charts contained information on the specifics of

Table 2 Cases of postoperative bracial plexopathy following open heart surgery. Initial presentation: motor, 1=paralysis, 2=paresis, 3=no weakness; sensory, 1=anaesthesia, 2=hypoaesthesia, 3=normal sensation; pain, 1=frank pain 2=dysaesthesia, 3=no pain. intraoperative positioning or arm positioning. None of the patients had undergone regional anaesthesia of the neck or upper extremity. All operations were of more than 2 h duration but there was no correlation between duration and long-term outcome. Because of the retrospective nature of the study and the limited method of case collection, no attempt was made to estimate incidence data from the total number of surgical cases over this period.

In the OHS group, seven of eight patients achieved full recovery over a median of 10 (range 4–16) weeks. One patient, a diabetic, suffered from a persistent tingling sensation in the affected hand. All had suffered injury to the roots of the lower trunk (C8, T1) with two also having injury to the middle trunk (C7). In the NCS group, three of 14 patients failed to achieve full recovery although all patients improved substantially. Injuries included roots of upper and middle trunks in all but one patient (No. 18). Three patients (Nos 3, 11 and 15) had injury inclusive of all roots of the plexus. For patients who recovered fully, the median time to recovery was 20 (range 8–50) weeks after operation. Six patients had no evidence of motor improvement by 6–8 weeks after operation and were studied by EMG. This continued evaluation, and a prior history of thoracic outlet syndrome, led to scalenectomy in patient No. 18, the result of which was complete neurological recovery. Age had no apparent influence on the likelihood of residual injury. All four patients with residual injury were male. While suggestive of an influence of gender on outcome (non-significant by Fisher's exact test) the small number of patients precluded meaningful statistical analysis. The same was true for the influence of "predisposing factors"; nine of 22 patients had some predisposing factor (see table 1) and two had a history of prior carpal tunnel release. It is uncertain if this is any different from the incidence of such factors in the general population of surgical patients. Of the four patients with residual injury, two had no predisposing factors and two were diabetic. That two of three diabetics with PBP had residual injury may suggest a poorer prognosis among diabetics.

The clinical presentation differed between OHS and NCS groups. In the former, sensory impairment and pain–dysaesthesia were the prominent and consistent features. No patient had isolated or predominant motor loss and six of eight patients had sensory–pain disturbance without motor loss or of greater degree than the motor loss. In the NCS group the opposite was true. Here, motor deficit was the prominent and consistent feature. There appears to be no indication of prognosis in the particular degree and features of the initial presentation. The one exception to this was for NCS-PBP where patients with pain–dysaesthesia tended to have a prolonged recovery. Further, all three patients with residual injury had pain–dysaesthesia. Also, patients with injury to all roots tended to have incomplete or prolonged recovery.

Six NCS-PBP patients had no motor recovery by 6–8 weeks. This group included all three patients with residual injury; that is 50% of patients with no motor recovery by 6–8 weeks ultimately had a residual deficit. There were several other observations related to recovery; motor recovery proceeded in a caudad–cepahalad direction with the lower roots recovering sooner. Sensory recovery appears to precede motor recovery and failure to observe any sensory recovery by 3–4 weeks may also be an ominous prognostic milestone. *All* patients exhibited significant recovery even if recovery was not complete; temporal progression was always in the direction of recovery with no patient exhibiting deterioration. No patient in this series suffered chronic pain.

Discussion

The most striking finding of this study was the disparate outcomes for the OHS compared with the NCS group. Although there was no significant difference in the quantitative incidences of residual injury (one of eight patients compared with three of 14 patients) there was a *qualitative* difference. In the OHS group, one of eight patients suffered a mild residual tingling sensation whereas in the NCS group, three of 14 suffered residual weakness. These values are in contrast with existing opinion that nearly all intraoperative brachial plexus injuries recover, and perhaps explains the prevalence of this complication in the insurance industry data.

It must be acknowledged that our methodology of case collection skewed the prognostic significance of these data to the pessimistic. A retrospective review of only those cases presenting to the hand clinic more than 1 week after operation eliminates those cases of mild and transient injury and may preferentially select those cases of motor complaint over those with sensory complaint. It has been reported that most cases of PBP after sternotomy are already asymptomatic at the time of hospital discharge.[13] Parks[6] reported 25 cases of PBP of whom eight suffered mild injury and recovered in an average time of 9 days. Of the remaining 17 patients, 14 recovered within 6 months and three had residual injury. Presumably our method of data collection would have missed 94% (if not all) of the cases of Tomlinson and colleagues[13] and 32% of Parks' cases.[6] It is therefore impossible to judge what fraction of *all* cases of PBP actually went on to referral to the hand clinic. The prognostic significance of our data therefore does not relate to all patients presenting immediately after operation with PBP, but rather to some subset of "worst cases". As a prognostic indicator these data are more representative of those patients with significant symptomatology 1 week after operation or at hospital discharge.

In the OHS cases of PBP the fact that all patients achieved full functional recovery in spite of this "worst case" selection suggests an extraordinarily good prognosis for this subset of cases. While most authors concur with this optimistic outlook for OHS-PBP, a prospective study of 1000 cardiac surgery patients found 55 cases of postoperative upper extremity disturbance of whom 28 recovered within several days, 19 recovered within 3 months and eight were still symptomatic 3 months after operation.[14] However, as follow-up did not extend beyond 3 months it is impossible to know the final disposition of these eight patients, and it is incorrect to assume that they suffered permanent injury. In our own series, three of eight OHS-PBP patients required 3 months or more to achieve full recovery.

Plexus injury after median sternotomy differs from PBP after NCS in several critical ways. First, PBP after OHS is far more common. As opposed to an incidence of 0.02–0.06% for NCS-PBP, the incidence of OHS-PBP in various prospective studies has ranged from a low of 1.9%[15] to 18.3%.[16] Electrophysiological evidence suggests the existence of subclinical injury in the majority of cardiac surgery patients.[17] Roy, Stafford and Charlton[18] summarized six prospective studies totalling 1772 patients undergoing OHS. The overall incidence of nerve injuries in these studies was 7.6% of which 80% (6.1%) were PBP. In their own prospective analysis of 162 cardiac surgery patients there were 12 (7.4%) cases of PBP.

OHS-PBP also differed from NCS-PBP in the distribution of the injury. Nearly all of the former involved lower roots of the plexus whereas the latter were typically lesions of the upper and middle roots. This generalization holds true throughout the literature and our data are consistent. The mechanism of injury in OHS-PBP is different (anatomically and mechanically) from that of NCS-PBP. The positioning of sternal retractors (cephalad placement promotes injury), extent of sternal retraction (excessive retraction promotes injury) and the wide, asymmetric sternal traction necessary for harvesting of an internal mammary artery graft pedicle have been associated with PBP.[14] Sternal retraction forces the clavicle into the retroclavicular space rotating the first rib superiorly and stretching the lower plexus.[19] Persistent changes in somatosensory evoked potentials associated with sternal retraction predict postoperative deficits.[20] On occasion, rib fracture may occur with the possibility of nerve penetration.[16 21] These fractures are common when evaluated by radionuclide bone scan although they are usually not detected by x-ray.[22] This mechanism may explain the more severe cases of OHS-PBP.

Another difference between OHS-PBP and NCS-PBP is in the clinical expression of the injury. Apart from the different anatomical distributions of the injuries, the presentation in NCS-PBP has been described as that of a relatively painless motor deficit which is greater in degree than sensory loss.[8] Our data supported the relative emphasis on the motor deficit in NCS-PBP. Where sensory deficit or pain–dysaesthesia presented in the NCS group it appeared to herald prolonged or incomplete recovery and an association with injury to the roots of the lower trunk in addition to those of the upper and middle trunks. For OHS-PBP the relative emphasis is on sensory disturbance as opposed to motor loss.[13 14] Our OHS-PBP patients also had primarily sensory complaints and 50% had no motor deficit.

An important difference between these two categories of PBP is that of prognosis. Although there are reported cases of persistent deficit after

OHS, the literature indicates a high likelihood of full recovery.[14 23–25] Our finding of seven patients with full recovery and one with only mild residual tingling (in spite of the "worst case" selection) is consistent with this. This compares with a less encouraging prognosis in the case of NCS-PBP.

Regarding the prognosis of OHS-PBP, most patients are already asymptomatic within several days.[13 14] In the study of Tomlinson and colleagues,[13] 94% were asymptomatic by the time of hospital discharge. Hudson, Boome and Sanpera[26] reported an incidence of 0.2% of OHS patients in their centre being referred to the hand clinic for PBP. Using the incidence data from prospective studies this implies that in their institution 96–98% of patients with OHS-PBP enjoyed rapid recovery. We estimate therefore that 90–95% of patients will be wholly or substantially improved within 1 month of surgery (with full recovery forthwith). Of those patients who have not substantially recovered by the 1 week "prognostic milestone" (our presumed criteria for referral to the hand clinic) our data suggest complete or near-complete recovery is highly likely. Most patients recover within several months, although on occasion recovery may be protracted (up to 1 yr) and, only rarely, incomplete.

In the case of NCS-PBP there are no prospective studies to allow a valid estimate of what percentage of patients have transient injury. Using the "1 week milestone" criteria, our data suggest that of those NCS-PBP patients with significant symptoms at 1 week, 79% (11 of 14) recover fully. This compares closely with Parks' finding of 82% (14 of 17 patients) full recovery. In assessing the individual patient there are no absolute markers of prognosis. However, this study suggests several possible portents to a slower recovery and worse outcome, including male gender, diabetes, injury to *all* roots of the plexus, and the presence of sensory deficit and pain or dysaesthesia. Absence of sensory recovery by 3–4 weeks and motor recovery by 6–8 weeks are further negative "prognostic milestones". Half of those patients with no motor recovery at 6–8 weeks ultimately suffered residual deficit. We stress that the data of this study are only *suggestive* and that the small number of patients involved precludes statistically significant conclusions. On the positive side, all patients achieved substantial, if not full, recovery. The role of physical therapy in this recovery cannot be overemphasized.

In summary, brachial plexus injury occurring after cardiac and non-cardiac surgery are two separate entities. The former is characterized by a predominance of sensory complaint in the lower roots of the plexus and the latter by a predominance of motor deficit in the upper and middle roots. The former is far more frequent than the latter, with an excellent prognosis for recovery. The prognosis of brachial plexopathy after non-cardiac surgery may be worse in males, diabetics, those with injury to all roots of the plexus and when, in addition to the motor deficit, there is sensory loss and pain or dysaesthesia. At a 1 week "prognostic milestone" 79% of symptomatic patients enjoyed complete recovery, although this took as long as 5 months or more in 50% of patients. In some, recovery took up to 1 yr. At the 6–8 week "prognostic milestone" 50% of those who had not yet shown evidence of improvement in the motor deficit suffered residual neurological deficit. However, all patients recovered to a significant extent even when recovery was not complete and none suffered from late deterioration or chronic pain. The relative infrequency of this serious complication and the paucity of our literature data base imply the need for further such series and perhaps ultimately their compilation through meta-analysis.

Does the addition of clonidine affect duration of analgesia of bupivacaine wound infiltration in inguinal hernia surgery?

S. ELLIOTT, S. ECKERSALL, L. FLIGELSTONE AND S. JOTHILINGAM

Summary

We conducted a prospective, randomized, double-blind study to compare analgesia obtained by wound infiltration using 29 ml of 0.25% bupivacaine alone, or with the addition of clonidine hydrochloride 150 μg. A third group received bupivacaine wound infiltration with clonidine 150 μg i.m. to control for the systemic effects caused by absorption of clonidine. We studied 46 adults undergoing elective inguinal hernia repair. The general anaesthetic technique, postoperative analgesia and wound infiltration technique were standardized. There was no difference in time to first analgesic request or to total analgesic consumption between the three groups during the 24-h study. Visual analogue scores (VAS) at rest and after coughing were noted over a 24-h period. The only difference was higher VAS scores at rest at 24 h in the control group who received i.m. clonidine. We conclude that for elective inguinal hernia repair, postoperative analgesia obtained by bupivacaine wound infiltration was not improved by the addition of clonidine 150 μg. (*Br. J. Anaesth.* 1997; **79**: 446–449).

Key words
Sympathetic nervous system, clonidine. Anaesthetics local, bupivacaine. Anaesthetic techniques, regional. Pain, postoperative.

Clonidine hydrochloride is an $alpha_2$ adrenoceptor agonist which has long been used to treat hypertension. In anaesthesia, clonidine given systemically has been found to decrease anaesthetic and analgesic drug requirements.[1] Later it was found that when mixed with local anaesthetic, clonidine extended the duration of both the motor and sensory elements of spinal,[2] extradural,[3] axillary,[4 5] femoral[6] and intercostal[7] nerve blocks.

As the synergistic effects of clonidine and bupivacaine have been recognized in a progressively peripheral manner, we attempted to continue this progression and show if it extends to the wound itself. Therefore, the purpose of this study was to examine if clonidine mixed with bupivacaine produced significant extension of postoperative analgesia obtained by performing wound infiltration during inguinal hernia repair.

Patients and methods

We studied 46 consecutive adult patients presenting for elective unilateral inguinal hernia repair in a double-blind randomized study. The study was approved by the local Ethics Committee and Medicines Control Agency, and written informed consent was obtained from all patients. Exclusion criteria included: patients receiving alpha adrenergic blocking drugs, those with Raynaud's disease or thromboangiitis obliterans (caution is recommended as clonidine has been reported to cause a condition resembling Raynaud's phenomenon), contraindications to the general anaesthetic technique or age less than 16 yr. Operations for recurrent hernia were excluded as the degree of dissection and thus tissue trauma would be expected to be greater than for first repairs.

All patients received the same general anaesthetic. Temazepam 10–20 mg was given orally 1 h before surgery. Anaesthesia was induced with propofol 2–3 mg kg^{-1} and maintained with isoflurane and nitrous oxide in oxygen. Analgesia was provided with fentanyl 1–2 μg kg^{-1}. The airway was maintained with a laryngeal mask airway. Vecuronium was used to facilitate mechanical ventilation using a Drager Narkomed ventilator. Datex Cardiocap and Capnomac monitors were used to monitor non-invasive arterial pressure, electrocardiogram, pulse oximetry and blood-gas analysis.

Using envelope randomization, patients were allocated to one of three groups before surgery. During surgery, all patients received a 30-ml study mixture infiltrated into the wound and an i.m. injection was given by the anaesthetist into the contralateral deltoid muscle. This injection was either clonidine or saline, to control for any systemic effects of clonidine. Patients in group A underwent wound infiltration with bupivacaine 29 ml and 0.9% saline 1 ml, in addition to an i.m. injection of 0.9% saline 1 ml. Patients in group B underwent wound infiltration with bupivacaine 29 ml and clonidine 150 μg (1 ml), with an i.m. injection of 0.9% saline 1 ml.

Patients in group C had wound infiltration with bupivacaine 29 ml and 0.9% saline 1 ml, with an i.m. injection of clonidine 150 μg (1 ml). A three-stage technique of wound infiltration before each stage of dissection was devised and performed by the surgeon. First, along the proposed line of incision, skin, subcutaneous fat and tissue deep to Scarpa's fascia were infiltrated. After skin incision, further infiltration through the external oblique aponeurosis was performed. Finally, there was direct infiltration to block ilio-inguinal and ilio-hypogastric nerves, and to the deep inguinal ring. The type of hernia repair was at the surgeon's discretion.

Postoperative analgesia was provided by two co-dydramol tablets 4–6 hourly and morphine 10–15 mg i.m. 3–4 hourly if required for severe pain.

Patient randomization and preparation of the test mixture were performed by an investigator who did not act as observer subsequently. The patient, surgeon and all other medical and nursing staff were blinded to the patient's treatment. Patient data were recorded by the ward nurses and the acute pain sister, and included: time to first dose of analgesic after operation and total analgesic requirements after operation; and visual analogue pain scores (VAS) at rest and on coughing, recorded in recovery and 6 and 24 h after operation. Patients was asked to indicate the degree of pain on a 10-cm line scale without gradations, the two ends marked "no pain" and "worst imaginable pain". The type of surgical repair and duration of operation were recorded, together with any complications which required treatment.

Parametric data were expressed as mean (SD) and analysed using analysis of variance with Bonferroni multiple comparison test. Non-parametric data were expressed as median (range) and analysed using the Kruskal–Wallis test followed by Dunn's multiple comparison test. Proportional data were analysed using the chi-square test. Results were considered significant at the 5% level.

Results

Results were obtained for 46 patients; 16 patients in group A, 15 in group B and 15 in group C. The three groups were matched for age, sex, duration and type of surgery (table 1). There was no significant differences in the time to first analgesia or total analgesic consumption (table 2). There was no difference between the rate at which patients in each group first requested analgesia (fig. 1) or the number requiring no analgesia.

Although not statistically significant, the addition of clonidine to bupivacaine appeared to confer an initial advantage in terms of VAS in the initial recovery period, although this was not apparent at 6 or 24 h (table 3). The only significant difference in VAS between groups was at rest 24 h after operation when the score for group C (3.9, range 0–8.4) was significantly higher than those in groups A (2, range 0–6.6) and B (1.2, range 0–6) ($P<0.05$ Kruskal–Wallis test).

Table 1 Patient data and operative details (mean (SD or range) or number)

	Group A	Group B	Group C
Age (yr)	62.2 (16.6)	66.4 (12.7)	59.8 (17.5)
Sex (M:F)	16:0	14:1	15:0
Repair (mesh:non-mesh)	14:2	11:4	13:2
Duration of operation (min)	54.8 (15.5)	61.2 (26.5)	56.3 (20.5)

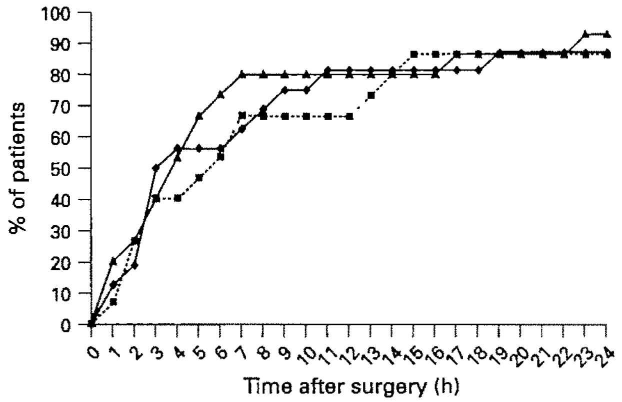

Figure 1 Percentage of patients requiring analgesia in the 24 h after inguinal hernia repair in group A (◆), group B (■) and group C (▲).

Table 2 Postoperative analgesic requirements in the first 24 h after inguinal hernia surgery. Data are median (range) except where indicated

	Group A	Group B	Group C
Total morphine (mg)	0 (0–10)	10 (0–30)	10 (0–20)
Total co-dydramol (tablets)	4 (0–6)	2 (0–8)	4 (0–6)
Time to first analgesia (min) (mean (SD))	392 (418.8)	499 (469.9)	418 (466.9)
No analgesia required	1:15	2:13	1:14

Table 3 Visual analogue scores (VAS) in the first 24 h after inguinal hernia surgery (median (range)). $^*P<0.05$ (Kruskal–Wallis)

	Group A	Group B	Group C
VAS at rest in recovery	0.85 (0–5.3)	0 (0–4.5)	2.8 (0–7)
VAS on coughing in recovery	2.1 (0–7.6)	1.3 (0–8.1)	3.55 (0–7.1)
VAS at rest 6 h postop.	1 (0–8.3)	1.6 (0–4)	1.5 (0–8)
VAS on coughing 6 h postop.	2.35 (0–8.5)	4.75 (0–6.2)	3.3 (0–9.4)
VAS at rest 24 h postop.	2 (0–6.6)	1.2 (0–6)	3.9 (0–8.4)*
VAS on coughing 24 h postop.	3.5 (0–7.5)	4.4 (0.7–10)	5.6 (1.7–10)

There was a higher incidence of adverse side effects in group C (three patients had bradycardia, associated with hypotension in two) requiring treatment with atropine and i.v. fluids. One patient in group B had bradycardia. No morbidity was noted in group A.

Discussion

We chose elective hernia surgery for this study as wound infiltration is well established as an effective method of providing postoperative analgesia[8–10] and indeed as the sole anaesthetic. The benefit of wound infiltration in other operations, for example appendicectomy, is less well demonstrated, perhaps because of the major contribution to postoperative pain of residual localized peritonitis. As there is no clear end-point to injection, we devised a standardized technique of wound infiltration which would provide a reliable distribution of local anaesthetic. This technique used pre-incisional infiltration as this has been shown to be more effective than postoperative infiltration.[11]

The addition of clonidine to local anaesthetic solutions has been shown to extend the duration of several peripheral nerve blocks. This appears to be a locally mediated effect, as it is not reproduced by systemically administered clonidine.[5] Gaumann, Brunet and Jirounek,[12] using the rabbit vagus nerve, showed that low concentrations of clonidine have an enhancing effect on lignocaine-induced inhibition of the C-fibre action potential. They suggested that this might explain the mechanism by which clonidine prolongs the action of lignocaine in peripheral nerve blocks. Singelyn, Gouverneur and Robert[4] have shown that unlike adrenaline which acts as a local vasoconstrictor, clonidine has no effect on the absorption of amide local anaesthetics from their site of action.

Although there was perhaps a trend towards improved pain scores in the immediate recovery period, we were disappointed to find that the addition of clonidine 150 μg to bupivacaine conferred no significant improvement in duration of postoperative analgesia after hernia surgery. It would appear that the conditions permitting a synergistic effect of clonidine and local anaesthetic present in major nerves are not present in the periphery. The nature of this difference is unclear and open to speculation, as there is little previous work in this area. Alternatively, the technique of wound infiltration itself may have confounded our investigation. Wound infiltration is difficult to study as, unlike neuroaxial or major nerve blocks, there is no directly measurable change in terms of motor or dermatomal block. Thus the effect of clonidine on bupivacaine wound infiltration was measured only indirectly in terms of time to first analgesia, total analgesic consumption and pain scores. It is well documented that analgesia derived from wound infiltration extends for a period far beyond the time when the local anaesthetic is present, particularly if a pre-incisional infiltration technique is used. Tverskoy and colleagues[9] demonstrated improved analgesia compared with general or spinal anaesthesia even 10 days after operation. Therefore, a possible reason for our negative findings may have been that any extension in the pharmacological action of local anaesthetic by clonidine was concealed by the prolonged analgesia provided by wound infiltration itself. It should be noted that even in control group A, the mean time to first analgesia exceeded 6 h. Infiltration of the wound produces prolonged analgesia possibly by pre-emptively blocking hyperalgesia and central nervous system hyperexcitability or "wind-up" caused by surgical trauma. Also, an anti-inflammatory action of amide local anaesthetics has been described.[13]

The only significant difference between groups was increased pain scores in group C at rest at 24 h. The relevance of this finding is questionable as 24 h is far in excess of the expected duration of action of clonidine. To confirm this finding would require further studies.

Failure to demonstrate significant differences between groups raises the possibility of type II statistical error. We conducted a *post hoc* power analysis using two assumptions. First, we considered that an important clinical difference between any two techniques would be reflected by a difference of 3.0 cm in the mean linear analogue pain scores between groups. Second, we used pooled data from the study to estimate a population SD. Using a 5% level of significance, we found that 15 patients per group yielded a power of 89%.

We used clonidine 150 μg as the majority of experience in regional anaesthesia is with this dose.[2 3 5–7] Higher doses may have revealed a peripheral effect, but may also have resulted in an increased incidence of systemic side effects.

In our hospital, hernia repair is a day surgery procedure. As our study was performed on inpatients, our study group consisted of patients with physical or social reasons requiring an overnight stay. This is reflected in the mean age of 62.7 yr in our study group. We decided to study only inpatients as clonidine is known to sometimes cause delayed sedation, hypotension and bradycardia.

In summary, addition of clonidine 150 μg to 0.25% bupivacaine wound infiltration conferred no improvement in either the quality or duration of postoperative analgesia after hernia surgery.

Comparison of suxamethonium and different combinations of rocuronium and mivacurium for rapid tracheal intubation in children†

M. NAGUIB, A. H. SAMARKANDI, A. AMMAR AND A. TURKISTANI

Summary

The use of suxamethonium in children is associated with undesirable side effects. The synergistic effect of a rocuronium–mivacurium combination can be considered as an acceptable alternative to suxamethonium in clinical practice. The calculated ED_{50} of the rocuronium–mivacurium mixture was only 62% of the predicted value assuming a purely additive interaction. The use of this combination has not been evaluated in children. In this two-part study, we assessed the intubating conditions and pharmacodynamics of suxamethonium, rocuronium, mivacurium or a rocuronium–mivacurium combinations in children. We studied 120 ASA I children of both sexes, aged 3–10 yr. Children were premedicated with trimeprazine 2 mg kg^{-1} orally, and received fentanyl 2 μg kg^{-1} and propofol 2 mg kg^{-1} for induction of anaesthesia. They were allocated randomly to receive one of the following drugs or drug combinations: suxamethonium 1.0 mg kg^{-1}, mivacurium 0.2 mg kg^{-1}, rocuronium 0.6 or 0.9 mg kg^{-1}, mivacurium 0.1 mg kg^{-1} with rocuronium 0.3 mg kg^{-1}, or mivacurium 0.15 mg kg^{-1} with rocuronium 0.45 mg kg^{-1}. In part 1, 60 s after administration of the neuromuscular blocking drug or drug combination, tracheal intubation was performed in 60 children by mimicking rapid sequence induction, and intubating conditions were evaluated by a blinded investigator according to a standard score. In part 2, neuromuscular monitoring was established before administration of neuromuscular blocking agent(s) and the time from injection of drug or drug combination until complete ablation of T1 (onset) and recovery of T1 to 25% (duration) were recorded in another 60 children. The frequency of distribution of excellent or good intubating conditions in the higher dose of rocuronium and the combination groups were similar to those in the suxamethonium group, but significantly different ($P<0.05$) from those in the mivacurium group. Mean onset time was faster in the suxamethonium (55.1 (SD 11.4) s), rocuronium 0.9 mg kg^{-1} (70.5 (37.7) s), mivacurium 0.1 mg kg^{-1} with rocuronium 0.3 mg kg^{-1} (67 (35.9) s) and mivacurium 0.15 mg kg^{-1} with rocuronium 0.45 mg kg^{-1} (55 (26.7) s) groups compared with the mivacurium 0.2 mg kg^{-1} (116 (26.8) s) and rocuronium 0.6 mg kg^{-1} (97.9 (29) s) groups. This study demonstrated that the combination of rocuronium 0.45 mg kg^{-1} and mivacurium 0.15 mg kg^{-1} could possibly be considered as an acceptable alternative to suxamethonium when rapid sequence induction of anaesthesia is indicated in children because it provides uniform excellent intubating conditions and complete neuromuscular block in <60 s. (*Br. J. Anaesth.* 1997; **79**: 450–455).

Key words

Anaesthesia, paediatric. Interactions (drug), mivacurium. Interactions (drug), rocuronium. Neuromuscular block, suxamethonium. Neuromuscular block, mivacurium. Neuromuscular block, rocuronium. Intubation tracheal.

Because it has a brief onset of action and rapid recovery, suxamethonium is still the standard neuromuscular blocking drug for rapid sequence tracheal intubation. However, its use in children is associated with undesirable side effects[1–4] that resulted in the recent mandated changes in the suxamethonium package insert by the Food and Drug Administration.[5 6] This concern raises an important question on alternate approaches that are available to the clinician to enhance the onset of the available non-depolarizing neuromuscular blocking drugs.[7 8]

The onset of action of non-depolarizing neuromuscular blocking drugs can be accelerated by the use of high doses of an individual agent,[9 10] combinations of blockers[11] or by preceding the intubating dose with a priming dose of blocker.[12 13] These techniques, however, have not consistently achieved the rapid onset of action of suxamethonium and did not result in uniform intubating conditions matching those after suxamethonium.

Rocuronium and mivacurium are non-depolarizing neuromuscular blocking agents that have recently been introduced into clinical practice. Rocuronium has a brief onset and an intermediate

†The results of this study were presented at the 6th International Neuromuscular Meeting, Paris, August 22–24, 1997.

duration of action. Mivacurium has a considerably shorter duration of action than any other currently used non-depolarizing agent. The speed of onset of rocuronium at the recommended intubating dose (0.6 mg kg^{-1}) is slower than that of suxamethonium.[10 13] Naguib[14] demonstrated that mixtures of rocuronium and mivacurium are synergistic in humans. The calculated ED_{50} of a rocuronium and mivacurium mixture (38.8 μg kg^{-1} for rocuronium and 11.4 μg kg^{-1} for mivacurium) was only 62% of the predicted value (125 μg kg^{-1} for rocuronium and 37 μg kg^{-1} for mivacurium) assuming a purely additive interaction.[14]

Because of the dangers of hyperkalaemic cardiac arrest after suxamethonium in children with unrecognized muscular dystrophy,[1–4] there have now been moves to limit the use of suxamethonium in children.[7 8] Hopkins[8] has indicated that there would be good reason not to use suxamethonium if another drug had the same advantages with fewer side effects. Therefore, the use of a rocuronium–mivacurium combination may be a reasonable alternative to suxamethonium for rapid sequence induction in children.

This two-part study was designed to assess the intubating conditions of single bolus doses of suxamethonium, rocuronium, mivacurium or different combinations of rocuronium and mivacurium in a simulated rapid sequence induction in children, and to measure onset time and duration of action of the drugs or drug combinations. This study differs from previous investigations because it included the suxamethonium group as a control, and because it compared multiple doses of rocuronium and different combinations of rocuronium and mivacurium under clinically relevant conditions.

Patients and methods

After obtaining institutional approval and informed consent from the children's parents, we studied 120 ASA I children of both sexes, aged 3–10 yr (mean 5.3 yr) and weighing 12–40 (mean 20.2 (SD 7)) kg. All patients were undergoing elective procedures, had no neuromuscular, renal or hepatic diseases, and were not receiving any drug known to interfere with neuromuscular function.

All patients received trimeprazine 2 mg kg^{-1} orally, and a local anaesthetic cream (EMLA, Astra Pharmaceuticals) was applied to the previewed puncture site 90 min before induction of anaesthesia. ECG, haemoglobin oxygen saturation by pulse oximetry (Sp_{O_2}) and arterial pressure were monitored. Temperature was monitored by a nasopharyngeal thermistor and maintained at 36.5±0.5 °C.

PART 1: RAPID SEQUENCE INDUCTION STUDY

In the first part of the study we compared the quality of neuromuscular block induced by different drugs in the context of rapid sequence induction. Sixty children were allocated randomly to one of six groups ($n=10$ in each) to receive suxamethonium 1.0 mg kg^{-1} ($2\times ED_{95}$)[15] (control group), mivacurium 0.2 mg kg^{-1} ($2\times ED_{95}$), rocuronium 0.6 mg kg^{-1} ($2\times ED_{95}$), rocuronium 0.9 mg kg^{-1} ($3\times ED_{95}$), mivacurium 0.1 mg kg^{-1} ($1\times ED_{95}$) with rocuronium 0.3 mg kg^{-1} ($1\times ED_{95}$), or mivacurium 0.15 mg kg^{-1} ($1.5\times ED_{95}$) with rocuronium 0.45 mg kg^{-1} ($1.5\times ED_{95}$). After preoxygenation with 100% oxygen for 3 min, anaesthesia was induced with fentanyl 2 μg kg^{-1} and propofol 2 mg kg^{-1} followed by the neuromuscular blocking drug or drug combination. Neuromuscular blocking drugs or drug combinations were injected over 5 s. When a combination of drugs was used, each was administered simultaneously by the same i.v. route. To maintain blinding, patients who received a single neuromuscular blocking drug had a simultaneous injection of a placebo (0.9% sodium chloride). Sixty seconds after the end of injection, the trachea was intubated in all patients by the same experienced anaesthetist who was unaware of the patient's grouping. He assessed intubating conditions using the following criteria[16]: excellent=jaw relaxed, vocal cords abducted and immobile, and no diaphragmatic movement; good=jaw relaxed, vocal cords abducted and immobile, and some diaphragmatic movement; poor=jaw relaxed, vocal cords moving, and coughing or bucking; and inadequate=jaw not relaxed and vocal cords closed. Cricoid pressure was applied during insertion of the tube. The ulnar nerve was stimulated supramaximally at the wrist with square pulses of 0.2 ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz every 12 s, using a Myotest peripheral nerve stimulator (Biometer International, Odense, Denmark). The resultant contraction of the adductor pollicis muscle was evaluated by tactile assessment of thumb adduction by another investigator. The number of contractions (TOF count) felt at the time of intubation was recorded.

PART 2: PHARMACODYNAMIC STUDY

In the second part of the study we investigated the time course of neuromuscular block induced by the drugs or drug combinations. Premedication and intraoperative monitoring were similar to that described in part 1. Anaesthesia was induced in all patients with fentanyl 2 μg kg^{-1} and propofol 2 mg kg^{-1}, and the lungs were ventilated via a face mask with 70% nitrous oxide in oxygen. After induction of anaesthesia, patients received a caudal injection of plain 0.25% bupivacaine 1 ml kg^{-1}. If more than 20 ml was used, the concentration of bupivacaine was reduced to 0.1875%. End-tidal concentration of carbon dioxide was maintained at 4.8–5.3 kPa. Incremental doses of propofol were administered as necessary to maintain unconsciousness. Concentrations of nitrous oxide, oxygen and carbon dioxide were measured continuously by a multiple-gas analyser (Capnomac, Datex Instrumentarium Corporation, Helsinki, Finland).

After loss of consciousness, an acceleration transducer (Biometer International, Odense, Denmark) was fastened to the volar side of the interphalangeal joint of the thumb. The ulnar nerve was stimulated supramaximally at the wrist with square pulses of 0.2 ms duration, delivered in a train-of-four (TOF) sequence at 2 Hz every 12 s, using a Myotest peripheral nerve stimulator (Biometer International, Odense, Denmark). The resultant contraction of the adductor pollicis muscle was recorded using a neuromuscular function analyser (Myograph 2000, Biometer International, Odense, Denmark). The first twitch (T1) of the TOF was considered the twitch height. The test hand was immobilized in a supine position using an arm board. Free movement during evoked thumb adduction was allowed by fixation of the extended four ulnar fingers by adhesive tape.

After a stable neuromuscular response was obtained, 60 children were allocated randomly to one of six groups ($n=10$ in each) to receive suxamethonium (control group), mivacurium, rocuronium, or a mivacurium–rocuronium combination in doses similar to those described in part 1. All drugs were administered as a single bolus dose over 5 s. When a combination of drugs was used, each was administered simultaneously by the same i.v. route. Tracheal intubation was performed at maximum block. Intubating conditions were not assessed in this part of the study. The times from injection of neuromuscular blocking drug or drug combination to complete ablation of T1 (onset time), from injection to recovery of T1 to 25% of baseline (clinical duration of action) and from recovery of T25–T75% (recovery index) were recorded.

In patients who received suxamethonium or mivacurium, a blood sample was obtained from an antecubital vein in the arm contralateral to that used for i.v. fluid administration for measurement of plasma cholinesterase (PCHE) activity, dibucaine and fluoride numbers. Plasma cholinesterase activity was measured by the change in absorbance at 600 nm after reduction of butyrylthiocholine to thiocholine, using BM/Hitachi 917, Boehringer Mannheim Diagnostics (Mannheim, Germany).

Intubating conditions were analysed by the Kruskall–Wallis test after assigning a numeric value to each intubation score. Dunnett's test was used to compare the suxamethonium (control) group with each of the other groups. Comparisons between groups who received rocuronium, mivacurium or a combination were carried out using the Student–Newman–Keuls multiple range test. Statistical analyses were carried out using BMDP statistical software (v. 7.01, University of California Press, Berkeley, CA, 1993). Results are expressed as mean (SD), and were considered statistically significant when $P<0.05$.

Results

There were no significant differences in distribution of age, weight or sex ratio between the groups (tables 1, 2). Similarly, dibucaine and fluoride numbers and baseline activity of PCHE were similar in all groups.

PART 1: RAPID SEQUENCE INDUCTION STUDY

The frequency of distribution of excellent or good intubating conditions in the higher dose of rocuronium and the combination groups were similar to those in the suxamethonium group, but significantly different ($P<0.05$) from those observed in the mivacurium group (table 1).

The number of TOF count felt at the time of intubation was significantly greater in the mivacurium, rocuronium 0.6 mg kg^{-1} and mivacurium 0.1 mg kg^{-1}–rocuronium 0.3 mg kg^{-1} groups compared with the suxamethonium group ($P<0.01$; Dunnett's test), rocuronium 0.9 mg kg^{-1} group or the mivacurium 0.15 mg kg^{-1}–rocuronium 0.45 mg kg^{-1} combination group ($P<0.05$; Student–Newman–Keuls multiple range test) (table 1).

PART 2: PHARMACODYNAMIC STUDY

Onset time was faster in the suxamethonium 1.0 mg kg^{-1}, rocuronium 0.9 mg kg^{-1} and combination groups compared with the mivacurium 0.2 mg kg^{-1} and rocuronium 0.6 mg kg^{-1} groups (table 2). Clinical duration and recovery index were shortest in the suxamethonium group compared with all other groups ($P<0.05$ or less). In patients who received non-depolarizing neuromuscular blocking drugs or drug combinations, clinical duration was longest in the rocuronium 0.9 mg kg^{-1} group ($P<0.05$) and shortest in the mivacurium 0.2 mg kg^{-1} group and mivacurium 0.1 mg kg^{-1}–rocuronium 0.3 mg kg^{-1} combination group ($P<0.05$). Recovery index was shortest ($P<0.05$) in the mivacurium group compared with the other groups who received rocuronium or drug combinations.

Discussion

We have assessed for the first time the potential of different doses of rocuronium and different combinations of rocuronium and mivacurium for rapid sequence induction in children compared with suxamethonium. This study demonstrated that children who received the combination of mivacurium 0.15 mg·kg^{-1} and rocuronium 0.45 mg kg^{-1} were similar to those who received suxamethonium in having uniform excellent tracheal intubating conditions and an onset of complete paralysis of <60 s. However, clinical duration of neuromuscular block was six times as long in the former group ($P<0.01$) compared with the suxamethonium group (25.3 (4.6) min *vs* 4.2 (1.4) min, respectively). In addition, a much larger SD for onset times was noted in the mivacurium–rocuronium combination groups compared with that after suxamethonium.

In part 1 of this study, we followed the strict clinical procedure of rapid sequence induction. Drugs that influence intubating conditions,[12 17 18] such as volatile anaesthetics, opioids or hypnotics, were not given to our patients after administration of the neuromuscular blocking drug or drug combination. In our patients, anaesthesia was induced with propofol. Although it has been suggested that propofol produces greater depression of pharyngeal and laryngeal reactivity than thiopentone,[19] this finding has not been substantiated by others.[18 20] In our study, the tracheas of all children were intubated successfully within 60 s after administration of the neuromuscular blocking drug or drug combination, and intubating conditions did not differ in patients who received either suxamethonium, rocuronium 0.9 mg kg^{-1} or the higher dose of the combination groups (table 1). Rocuronium 0.6 mg kg^{-1} did not produce as good intubating conditions as suxamethonium 1.0 mg kg^{-1} after 60 s. We noted also that mivacurium 0.2 mg kg^{-1} was not suitable for rapid tracheal intubation in children (table 1). Similar observations were reported by others even when doses up to mivacurium 0.3 mg kg^{-1} were administered in children.[21] Our results are in accordance with those reported by Fuchs-Buder and Tassonyi in children in whom tracheal intubation was carried out by mimicking rapid sequence induction.[16] They noted excellent intubating conditions in 83% and 94% of patients, 60 s after rocuronium 0.6 mg kg^{-1} and 0.9 mg kg^{-1}, respectively.[16] Woelfel and colleagues[22] found that intubating conditions 60 s after rocuronium in 12 children during steady state halothane anaesthesia were excellent in nine and good in three patients.

We found that complete neuromuscular block at the adductor pollicis muscle was not a prerequisite for optimal intubating conditions. In our study tracheal intubation was performed 60 s after administration of the neuromuscular blocking drug or drug combination, regardless of the degree of neuromuscular block. In adults, faster onset at the laryngeal compared with the peripheral muscles has been reported with suxamethonium, rocuronium and mivacurium.[23–25] However, the onset of action of rocuronium at the laryngeal adductor muscles is slower than that after suxamethonium, and the degree of block is less intense.[26] In this study, onset time in the rocuronium 0.9 mg kg^{-1} group was similar to that in the suxamethonium group (table 2). As the dose of rocuronium increased from 0.6 to 0.9 mg kg^{-1}, onset time for neuromuscular block decreased by 28% (from 97.9 to 70.5 s; $P<0.05$) and duration of action increased by 55% (from 23.7 to 36.4 min; $P<0.05$) (table 2). This was associated with a concomitant increase in the recovery index (table 2). Using electromyography (Relaxograph) during isoflurane anaesthesia, Fuchs-Buder and Tassonyi[16] demonstrated that increasing the dose of rocuronium from 0.6 to 0.9 mg kg^{-1} in children significantly decreased onset time (193 (47) *vs* 118 (23) s) and prolonged clinical duration (21 (4) *vs* 34 (11) min). In the latter study,[16] however, the investigators re-calibrated the Relaxograph after administration of rocuronium when steady state concentrations of the volatile anaesthetic were achieved.

The results of our study confirm our previously published data in adults that combinations of rocuronium and mivacurium produced a shorter onset time comparable with that of suxamethonium.[14] In this study, time to maximal neuromuscular block decreased from 97.9 to 67 s ($P<0.05$) and both clinical duration and recovery index decreased from 23.7 and 9.2 min to 15.2 ($P<0.05$) and 7.3 min, respectively, when rocuronium 0.3 mg kg^{-1} together with mivacurium 0.1 mg kg^{-1} were given instead of rocuronium 0.6 mg kg^{-1} alone. The clinical profile of this combination was similar to that reported with equipotent doses in adults (rocuronium 0.3 mg kg^{-1} and mivacurium 0.075 mg kg^{-1}) with respect to onset time (69 s) and recovery index (7.5 min).[14] However, the clinical duration was different—15.2 min in children (this study) *vs* 34 min in adults.[14] There may be pharmacokinetic reasons for the differences between adults and children. The pharmacokinetics of rocuronium in children aged 4–11 yr revealed an age-dependent increase in plasma clearance[27] that contributed to the shorter duration of action compared with infants or adults.[28] The increased cardiac output in children may also contribute to the shortened duration of action by removing the drug from the neuromuscular junction more rapidly than in adults.[29] These pharmacokinetic differences could explain the longer clinical duration of the rocuronium–mivacurium combination observed in adults compared with children.

We also noted that increasing the dose of the components in the combination—as in the rocuronium 0.45 mg kg^{-1}–mivacurium 0.15 mg kg^{-1} combination—resulted in a 44% and 22% shorter onset time than that produced by rocuronium 0.6 and 0.9 mg kg^{-1}, respectively (55 *vs* 97.9 and 70.5 s, respectively). The clinical duration observed with the latter combination (25.3 min) was similar to that seen with rocuronium 0.6 mg kg^{-1} (23.7 min), but was 30% shorter ($P<0.05$) than that noted with rocuronium 0.9 mg kg^{-1} (36.4 min) (table 2).

Effect of temperature and cardiopulmonary bypass on the pharmacokinetics of remifentanil

D. RUSSELL, D. ROYSTON, P. H. REES, S. K. GUPTA AND G. N. C. KENNY

Summary

Sixteen patients undergoing coronary revascularization requiring cardiopulmonary bypass received remifentanil 2 μg kg^{-1} or 5 μg kg^{-1} by infusion over 1 min after sternotomy but before commencing cardiopulmonary bypass, during hypothermic cardiopulmonary bypass and during cardiopulmonary bypass after rewarming. Hypothermic cardiopulmonary bypass reduced the clearance of remifentanil by an average of 20%, and this was attributed to the effect of temperature on blood and tissue esterase activity. Reductions in arterial pressure occurred with administration of both doses during normothermia only. (*Br. J. Anaesth.* 1997; **79**: 456–459).

Key words
Analgesics opioid, remifentanil. Pharmacokinetics, remifentanil. Heart, cardiopulmonary bypass. Temperature, effect. Surgery, cardiovascular.

Infusions of fentanyl, alfentanil and sufentanil have become established for use during induction and maintenance of anaesthesia in patients undergoing cardiac and vascular surgery.[1–3]

Remifentanil hydrochloride is a synthetic mu receptor agonist with an analgesic potency similar to that of fentanyl,[4] but with an ultra-short duration of action because of rapid hydrolysis by plasma and tissue esterases. Westmoreland and colleagues[5] investigated the pharmacokinetics of remifentanil in 24 ASA I–III patients undergoing elective surgery. They administered remifentanil 2, 5, 15 or 30 μg kg^{-1} over 1 min, and concluded that its pharmacokinetics were best described by a three-compartment model. The initial distribution half-life was approximately 30 s, intermediate disposition half-life 2–4 min and terminal half-life 10–20 min. Clearance was 250–300 litre h^{-1} (4.17–5 litre min^{-1}) and was independent of the dose of remifentanil administered, sex, body weight or age. Mean volume of distribution at steady state was 24.3–39.8 litre, with approximately 20% of this attributable to the central compartment.

GR90291, the major carboxylic acid metabolite of remifentanil, has 0.02% the potency of its parent molecule and is eliminated primarily by the kidneys.[6] Its pharmacokinetics have been shown to be linear, with a mean terminal half-life of 88.1–137.4 min.[5]

Dershwitz and colleagues[7] administered remifentanil 1 μg kg^{-1} over 1 min followed by infusion of 0.05–1.0 μg $kg^{-1}min^{-1}$ until the end of surgery in 29 patients after induction of anaesthesia with propofol. Despite the variation in infusion rate, the times to onset of spontaneous respiration after discontinuation of remifentanil were similar, suggesting that remifentanil was not rate limiting in recovery from anaesthesia.

Remifentanil might therefore be attractive for use in circumstances where varying degrees of intense opioid activity are required, and where after discontinuation of infusion of opioid, blood concentrations, and hence opioid receptor occupancy, decrease rapidly and predictably irrespective of the dose or duration of infusion. Another potentially attractive feature is that the pharmacokinetics of remifentanil are unlikely to be affected significantly by hepatic[8 9] or renal impairment.[10]

Esmolol is a short-acting β-adrenergic blocking agent which is metabolized extensively by esterases present in the cytosol of red blood cells.[11] Kramer and colleagues[12] investigated the pharmacokinetics of esmolol in patients undergoing cardiac anaesthesia and observed that clearance was reduced during hypothermic cardiopulmonary bypass (CPB). They attributed this to reduced enzymatic hydrolysis associated with hypothermia, and as remifentanil undergoes hydrolysis by similar enzyme systems we hypothesized that similar principles might apply. This might significantly affect remifentanil requirements during hypothermic CPB. The aim of this study was to assess the effect of temperature and CPB on the pharmacokinetics and pharmacodynamics of remifentanil in patients undergoing coronary revascularization.

Patients and methods

After obtaining Ethics Committee approval, 16 male or female patients, aged 18–65 yr, undergoing elective coronary revascularization requiring CPB gave written informed consent to take part in the study. Exclusion criteria were a recent history of unstable angina or myocardial infarction, significant left main stem coronary artery disease, significant valvular heart disease, significant hepatic or renal disease, recent history of major opioid use, personal or family history of cholinesterase deficiency and obesity (greater than 25% above ideal weight for height).

Concomitant cardiovascular medication was continued up to and including the day of surgery. Patients received benzodiazepine–opioid premedication and anaesthesia was induced and maintained using an opioid–hypnotic–neuromuscular blocker technique. In all cases the CPB pump was primed with 2 litre of crystalloid, diastolic cardiac arrest was induced with cold crystalloid cardioplegia, and during CPB arterial blood pH was maintained at 7.4 (measured at 37 °C).

REMIFENTANIL ADMINISTRATION

Remifentanil was delivered from a motorized syringe driver over 60 s via a central venous catheter into the superior vena cava. Each patient was scheduled to receive three i.v. bolus doses of remifentanil, at distinct times during surgery.

Period A (normothermic, pre-bypass) after sternotomy but before commencing CPB, with a core (nasopharyngeal) temperature >35 °C.

Period B (hypothermic, on bypass) during hypothermic CPB, with a core temperature of 28–30 °C for at least 15 min.

Period C (normothermic, on bypass) before discontinuation of CPB, with a core temperature of >36 °C for at least 5 min.

The study had a dose escalation design, with the first eight patients receiving three bolus doses of 2 μg kg^{-1}, and the remaining eight patients receiving three doses of 5 μg kg^{-1}. Haemodynamic indices were recorded during the period immediately after administration of remifentanil.

SAMPLE COLLECTION AND ANALYSIS

Blood samples (5 ml) were obtained from a radial artery cannula immediately before administration of remifentanil, and at 1, 2, 3, 4, 5, 10, 15, 20 and 30 min after the start of administration or until the criteria for periods A, B or C no longer applied (mainly discontinuation of CPB). The samples were heparinized and two duplicate 2.5-ml aliquots were placed in tubes containing 50 μl of 50% citric acid. Each tube was vortexed vigorously for 10 s, inverted several times and frozen at −20 °C. Concentrations of remifentanil in whole blood were measured by GC high resolution mass spectrometry, with a lower limit of detection of 0.1 ng ml^{-1}. The inter-day coefficient of variation was less than 8.5% at 0.25 ng ml^{-1}, and 4.6% at 80 ng ml^{-1}.

Compartmental data analysis involved fitting the blood concentration–time data for each phase to a two- or three-compartment model with zero order input rate using the non-linear least squares regression analysis program PCNONLIN.[13] A weighting scheme of $1/C_{\text{predicted}}$ was used. The choice of $1/C_{\text{predicted}}$ rather than $1/C_{\text{observed}}$ was made because we believe that the true variance of the observations (and hence the weighting) is estimated better from the entire data set (the model predicted values) than from an individual observation. Model selection was based on the following goodness of fit measures: visual inspection of the residual plots, magnitude of the standard error of variable estimates and Akaike's information criteria.[14]

Comparison between dose groups (2 and 5 μg kg^{-1}) was conducted using the two sample *t* test (SAS PROC TTEST) on un-transformed and log-transformed variables, and with a non-parametric method (Wilcoxon Rank Sum, SAS PROC NPAR/WA). Treatment group comparisons (normothermia pre-bypass compared with hypothermic CPB) were conducted using analysis of variance of un-transformed data (SAS PROC GLM).

Results

PHARMACOKINETIC DATA

The pharmacokinetics of remifentanil 2 μg kg^{-1} were determined in eight patients during period A (pre-bypass, normothermia), in seven patients during period B (CPB, hypothermia) and in four patients during period C (CPB, normothermia) (table 1). Results were obtained in eight, seven and

Table 1 Mean (SD) pharmacokinetic variables following administration of remifentanil 2 μg kg^{-1} during period A (pre-bypass, normothermia), period B (cardiopulmonary bypass (CPB), hypothermia) and period C (CPB, normothermia). $t_{1/2}^{\lambda 1}$=distribution half-life, $t_{1/2}^{\lambda 2}$=elimination half-life, V_1=volume of distribution (central compartment), V^{SS}=volume of distribution at steady state, *Cl*=clearance.

six patients receiving remifentanil 5 μg kg^{-1} during periods A, B and C, respectively (table 2). Remifentanil concentrations immediately before the doses administered during bypass were at or below the limit of analytical detection and were therefore considered to be zero. The fraction AUC extrapolated using the two-compartment terminal elimination rate constant was less than 20%.

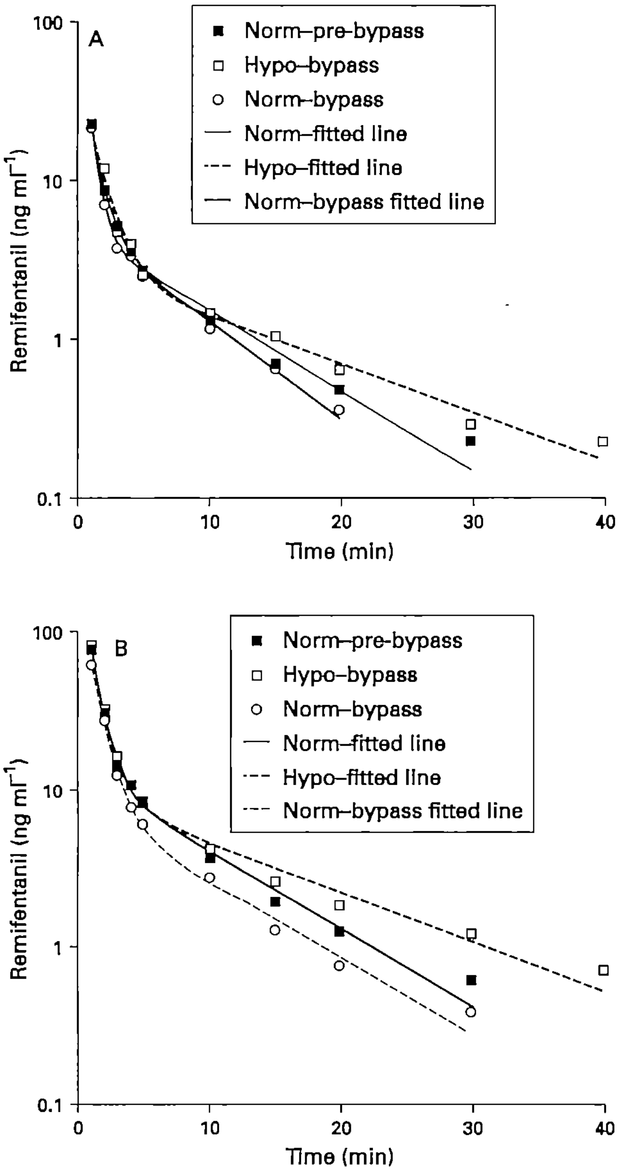

Figure 1 A: Mean blood concentration–time profiles after administration of remifentanil 2 μg kg^{-1}. B: Mean blood concentration–time profiles after administration of remifentanil 5 μg kg^{-1}.

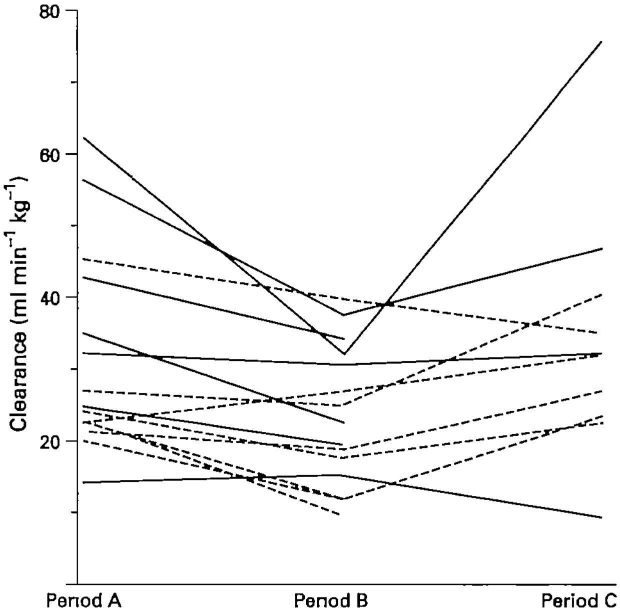

Figure 2 Clearance of remifentanil after administration of 2 μg kg^{-1} (---) and 5 μg kg^{-1} (——) during period A (pre-bypass, normothermia), period B (cardiopulmonary bypass (CPB), hypothermia) and period C (CPB, normothermia).

Blood remifentanil concentration–time profiles were fitted to a two- or three-compartment pharmacokinetic model. Statistical evaluation of the goodness of fit demonstrated that the three-compartment model offered no significant improvement over the two-compartment model. Therefore, the data were represented by a two-compartment model for further comparison between dose groups and treatment periods.

There were no significant differences in the pharmacokinetics of remifentanil between the two dose groups (ANOVA; $P>0.05$). Data for the two groups were therefore pooled and are shown in table 3. Mean blood concentration–time profiles for the two doses are shown in figure 1A and 1B. Clearance of remifentanil was similar in periods A and C (fig. 2), but was reduced by an average of 20% during period B compared with period A in the same individuals (ANOVA; $P=0.0057$). This was attributed to reduced hydrolytic enzyme activity at the lower temperatures associated with hypothermic CPB. No significant difference in volume of distribution at steady state (V^{ss}) was detected between treatment periods.

HAEMODYNAMIC DATA

Brief reductions in arterial pressure of 14–25% occurred during periods A (fig. 3) and C after administration of remifentanil 2 and 5 μg kg^{-1}. Mean arterial pressure was unchanged during period B with both doses. No clinically relevant alterations in heart rate occurred with administration of remifentanil at either dose.

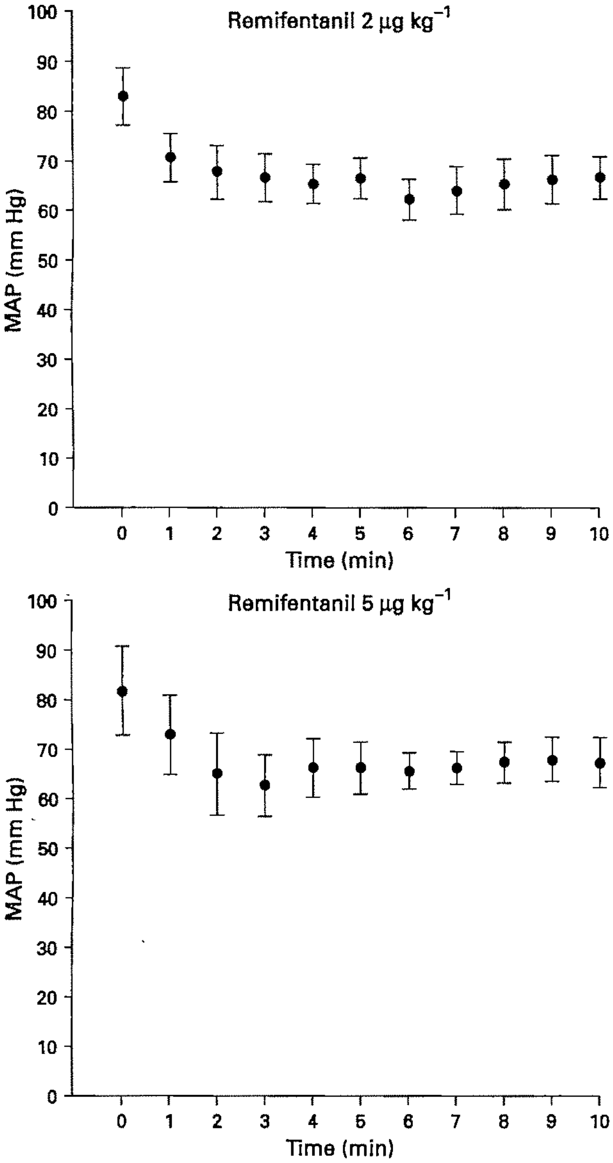

Figure 3 Mean (SD) mean arterial pressure (MAP) after administration of remifentanil 2 or 5 μg kg^{-1} during the period between sternotomy and commencing cardiopulmonary bypass. Remifentanil was administered over 60 s between 0 and 1 min.

Discussion

The mean value for clearance of remifentanil in the 2-μg kg^{-1} dose group was consistent with that observed in previous studies, while the value observed after administration of 5 μg kg^{-1} was somewhat lower than typically seen. Previous studies[5,15] with remifentanil have demonstrated linear pharmacokinetics over a wide range of doses in both healthy volunteers and anaesthetized patients. Therefore, we believe that the lower clearance in the 5-μg kg^{-1} group reflected inter-patient variability in a study of this nature using eight patients in each group, rather than being caused by dose-dependent (non-linear) pharmacokinetics. As such, we considered using pooled data from the two groups to be appropriate. The pooled dose group analysis was consistent with the individual group analyses and demonstrated a modest, but consistent, reduction in remifentanil clearance during hypothermic CPB compared with matched pre-bypass values.

As the pharmacokinetics of remifentanil were only modestly altered by hypothermic CPB, administration of remifentanil during cardiac anaesthesia can therefore be based on anticipated or observed patient need without the concern for major dosage adjustment during bypass.

Influence of pulse oximeter lower alarm limit on the incidence of hypoxaemia in the recovery room†

A. T. RHEINECK-LEYSSIUS AND C. J. KALKMAN

Summary

In a prospective, randomized study, we have investigated the effects of two arbitrary pulse oximeter lower alarm limit (LAL) settings (90%=group 90, n=320 and 85%=group 85, n=327) on the incidence of hypoxaemia in the recovery room. In group 90, we calculated the theoretical effect of elimination of transient episodes of low pulse oximeter oxyhaemoglobin saturation (Sp_{O_2}) by introducing a time delay between the onset of the alarm condition and triggering of the alarm. When only hypoxaemic episodes lasting more than 1 min were included, Sp_{O_2} ≤90% occurred in 11% of patients in group 90 and in 20% in group 85 (relative risk (RR) 1.84, confidence interval (CI) 1.26–2.69; P<0.01). Hypoxaemia ≤85% occurred in 2% of patients in group 90 and in 6% in group 85 (RR 3.10, CI 1.32–7.28; P<0.01). In group 90, 1007 alarms (33% false) occurred, whereas in group 85, 395 alarms (28% false) occurred. Introducing a theoretical delay of 15 s in group 90 between crossing the alarm threshold and triggering the alarm would have reduced the number of alarms by 60%. The results of the study suggest that decreasing the alarm limit in an attempt to reduce frequent false alarms may lead to an increase in more relevant episodes of hypoxaemia and setting the LAL at 85% cannot be recommended routinely. Introducing a 15 s delay in group 90 would reduce the number of alarms by the same amount as changing the LAL from 90% to 85%. (*Br. J. Anaesth.* 1997; **79**: 460–464).

Key words
Equipment, alarms. Oxygen, saturation Hypoxaemia. Equipment, pulse oximeters.

The rationale for pulse oximetry monitoring is the expectation that early recognition of hypoxaemia prevents critical respiratory events.[1 2] Because respiratory problems are common in the initial postoperative period, pulse oximetry monitoring has been accepted universally as a standard of care to alert personnel in the recovery room to impending hypoxaemia. Audible alarms have been incorporated in these monitors to anticipate or detect critical situations in an environment in which personnel must perform multiple tasks. An average frequency of pulse oximeter alarms in the recovery room of once every 8 min has been reported.[3] Another study showed that only 10% of alarms were clinically relevant.[4] Frequent clinically insignificant alarms have the potential to frustrate personnel, distract attention from more important tasks and can even result in unnecessary therapeutic interventions, neglect of true alarms or permanent disabling of the alarm.[5]

It is obvious that decreasing the pulse oximeter lower alarm limit (LAL) should reduce the number of alarms. However, it is uncertain if this would reduce its efficacy as a monitor of impending severe hypoxaemia. For sudden severe events there might be little difference. For example, when pulse oximeter oxyhaemoglobin saturation (Sp_{O_2}) decreases rapidly after the onset of respiratory arrest, the triggering of an alarm by an Sp_{O_2} of 90% or 85% may be only marginally different. None the less, many clinicians argue that decreasing the alarm limit might increase the incidence of hypoxaemia. The effects of LAL on the incidence and duration of hypoxaemia have not been evaluated. In a prospective, randomized study, we have investigated the effects of two arbitrary LAL settings (Sp_{O_2} 90% and 85%) on the incidence and duration of hypoxaemia in the recovery room. As an alternative to a LAL of 85%, the effect of maintaining the LAL at 90% and elimination of short-lasting alarms by introducing an alarm delay (a delay between Sp_{O_2} crossing the alarm threshold and triggering of the audible alarm) was calculated.

Patients and methods

We studied consecutive patients who entered the recovery room of a regional (non-teaching) hospital after general or regional anaesthesia over a 1-month period. The study was approved by the hospital

†Presented in part at the Annual Meeting of the American Society of Anesthesiologists, San Francisco, October 1994.

Ethics Committee and each patient gave informed consent to participate in the study. There were no exclusion criteria for age, ASA status or type of operation. Patients who required postoperative mechanical ventilation were excluded from the study. Institutional guidelines for anaesthetic and post-anaesthetic care did not change during the study. No bedside observer was present to verify the validity of the plethysmographic signal or to record the actions by the recovery room nurse.

PULSE OXIMETRY MONITORING

At the beginning of each day the LAL of each pulse oximeter (Criticare 504, Criticare Systems, Inc., Waukesha, WI, USA) was set randomly at either 90% (group 90) or 85% (group 85). The averaging epoch of each pulse oximeter was set at 3 s. A minimum value of the signal is required by the pulse oximeter to calculate Sp_{O_2} or else a loss of signal message is displayed. The display of this device shows the plethysmographic waveform, Sp_{O_2}, heart rate and alarm limits. A loud continuous audible alarm sounds when Sp_{O_2} decreases to or below the level of the LAL. It is possible to temporarily disable the alarm sound for a maximum of 2 min. Patients arriving from the operating room were allocated to the next available bed. Monitoring started immediately after arrival of the patient in the recovery room and was continued until the time of discharge. The sensor of the pulse oximeter was applied to a finger of the hand opposite to the arterial pressure cuff. Supplementary oxygen was administered by a nasal cannula to all patients during the initial postoperative period.

ANALYSIS OF ALARMS, ARTEFACTS AND HYPOXAEMIA

Heart rate, Sp_{O_2} and alarm status, together with time of day, were stored every 5 s in the memory of the pulse oximeter and transferred at the end of the day to a personal computer. Data for the first and last 3 min of monitoring were excluded to eliminate artefacts resulting from positioning and removal of the probe.

Episodes with Sp_{O_2} $\leqslant$90% were classified as hypoxaemia or artefact. An episode was classified as artefact if one or more of the following criteria were met:

—transient outlier: a single datum point (5 s resolution) differing by more than 4% from the surrounding data;

—loss of signal (as indicated by the pulse oximeter) occurring either 0–20 s before or 0–20 s after the episode of low Sp_{O_2};

—a step change in Sp_{O_2} of more than 10% in 5 s; and

—in an attempt to increase further the detection of artefacts, all other episodes with Sp_{O_2} $\leqslant$90% were inspected visually by the author (A. T. R-L., blinded for the group from which the data originated). If there was simultaneous jitter of Sp_{O_2} and heart rate, a movement artefact was suspected and data were classified as artefact.

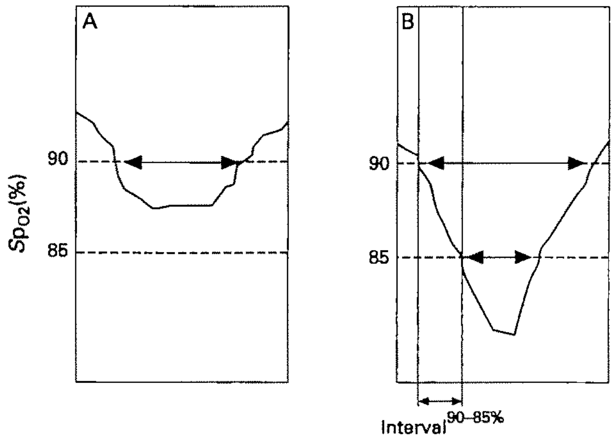

Figure 1 Examples of triggering of the alarm by low Sp_{O_2} values for two alarm limits (90% and 85%). In example A the episode triggers the alarm if the limit is set at 90%, but the episode resolves without having triggered the alarm if the limit is set at 85%. In example B the episode triggers the alarm with either limit, but the alarm is delayed if the limit has been set at 85%. Interval$^{90-85\%}$ denotes the time difference between Sp_{O_2} crossing the 90% threshold and the 85% threshold.

The number of episodes of hypoxaemia for the two thresholds (Sp_{O_2} $\leqslant$90% and $\leqslant$85%) was counted. Episodes where Sp_{O_2} decreased to values $\leqslant$90% were differentiated from those in which Sp_{O_2} remained above 85% (see example A in fig. 1) and from those where it decreased to less than 85% (example B in fig. 1). The time difference between Sp_{O_2} crossing the 90% threshold and the 85% threshold (interval$^{90-85\%}$) was calculated (example B in fig. 1).

The incidence of hypoxaemia (proportion of patients with at least one episode of hypoxaemia lasting $\geqslant$1 min) for three thresholds (Sp_{O_2} $\leqslant$90%, $\leqslant$85% and $\leqslant$80%) was determined. For each patient the cumulative duration of hypoxaemia (only episodes $\geqslant$1 min) for each of the thresholds was calculated.

Alarms were classified as either true positive (generated by hypoxaemia) or false positive (generated by artefact). In group 90 the effect on the number of alarms of introducing various theoretical delays (0–60 s, 5-s steps) between the onset of the alarm condition and triggering of the alarm was calculated.

Data are presented as counts and percentiles. Differences between the two groups were analysed using chi-square and Mann–Whitney tests. $P<0.05$ was considered significant. In group 85 the incidence of hypoxaemia was also expressed as relative risk (RR) compared with group 90. The confidence interval (CI) for relative risk was calculated with the Mantel–Haenszel chi-square statistic.

Results

During the 1-month period, we studied 647 patients; 320 patients were allocated to group 90 and 327 patients to group 85. Table 1 presents descriptive data for patients, anaesthesia and post-anaesthetic care. There were no differences between groups in

Table 1 Data on patients, anaesthesia and post-anaesthetic care. Data are counts or median (10–90th percentiles). Group 90=lower alarm limit of the pulse oximeter set at 90%, group 85=lower alarm limit of the pulse oximeter set at 85%

age, ASA status, duration of anaesthesia or post-anaesthetic care.

The incidence of hypoxaemia was greater in group 85 (table 2). Episodes of hypoxaemia ≤90% lasting for more than 1 min were present in 11% of patients in group 90 and in 20% of the patients in group 85 ($P<0.01$). Hypoxaemia ≤85% occurred in 2% of patients in group 90 and in 6% in group 85 ($P<0.01$). Hypoxaemia ≤80% occurred in 0.3% of patients in group 90 and in 2% in group 85 ($P=0.06$). The median cumulative duration of hypoxaemic episodes ≥1 min was not different between the groups (Sp_{O_2} ≤90%: 95 *vs* 175 s; Sp_{O_2} ≤85%: 165 *vs* 120 s).

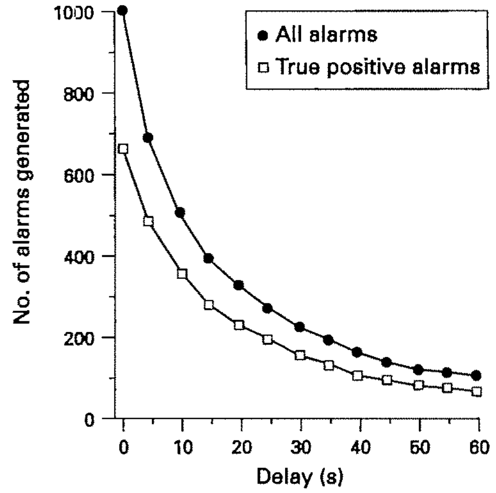

Figure 2 Number of alarms calculated that would have occurred when the lower alarm limit was set at 90% but a delay, which varies from 0 to 60 s, was introduced between the onset of pulse oximeter oxyhaemoglobin saturation below 90% and triggering of the alarm. The true positive alarms indicate hypoxaemia.

The number of episodes of desaturation ≤90% (without applying a criterion for the minimum duration of the episode) was 674 in group 90 and 938 in group 85. Sp_{O_2} decreased to or below 85% (see example B in fig. 1) in 104 desaturations in group 90 and in 197 desaturations in group 85. Table 3 shows the interval$^{90-85\%}$, the time required for oxyhaemoglobin saturation to decrease from 90% to 85%. The majority of desaturations less than 85% had an interval$^{90-85\%}$ less than 20 s in both groups. A longer interval$^{90-85\%}$ (≥20 s) occurred significantly more often in group 85 ($P<0.001$).

In group 90, 1007 alarms (674 true, 333 false) occurred, whereas in group 85, 395 alarms (285 true, 110 false) occurred. Figure 2 shows the number of alarms in group 90 that would have occurred with various delays from 0 to 60 s between the onset of the alarm condition (Sp_{O_2}=90%) and triggering of the alarm. As 60% of alarms lasted 15 s or less, introducing a 15-s delay in group 90 would reduce the number of alarms by the same amount as changing the LAL from 90% to 85% (group 90 with 15 s delay—398 alarms (71% true, 29% false) and group 85 with no delay—395 alarms (72% true, 28% false)).

Table 3 Time required for oxyhaemoglobin saturation to decrease from 90% to 85%. Group 90=lower alarm limit of the pulse oximeter set at 90%, group 85=lower alarm limit of the pulse oximeter set at 85%, Sp_{O_2}=oxyhaemoglobin saturation, interval$^{90-85\%}$=time difference between Sp_{O_2} crossing the 90% threshold and the 85% threshold

Discussion

Lowering the LAL from 90% to 85% is an effective means of reducing the number of audible alarms in the recovery room. However, with the LAL set at 85% the incidence of hypoxaemia lasting more than 1 min increased. Although the clinical relevance of this finding is unknown,[6] most clinicians would consider episodes of hypoxaemia of less than 85% lasting greater than 1 min potentially harmful. Therefore, based on the results of this study, setting the LAL at 85% cannot be recommended routinely.

Postoperative hypoxaemia has been implicated as a contributing factor for myocardial ischaemia, wound infection and cognitive dysfunction.[7–11] However, a large prospective study failed to demonstrate significant effects of pulse oximetry on outcome.[12 13] To increase the clinical relevance of a possible effect of the chosen LAL, we studied episodes with a minimum duration of at least 1 min. The six times higher incidence of severe hypoxaemia $\leqslant$80% in group 85 was not statistically significant (P=0.06). To exclude a type II error (a difference exists, but was not found in this study) a calculated group size of more than 2000 patients would be needed to achieve 80% power to detect a 50% reduction. This suggests that groups larger than the 320 patients we studied would have shown a statistically significant increased incidence of hypoxaemia $\leqslant$80% in group 85 also.

An alarm should initiate an intervention to reverse the ongoing desaturation. In addition, the underlying cause of the desaturation must be treated. In group 85 the majority of desaturations less than 90% resolved without triggering an alarm. However, the total number of these desaturations (in which the lowest Sp_{O_2} remained >85%, see example A in fig. 1) was 40% higher than in group 90. This suggests that the alarms resulted in therapeutic actions that corrected the underlying cause and prevented subsequent hypoxaemia.

In this study the speed of desaturation (as measured by the interval$^{90–85\%}$) was rapid in the majority of patients in both groups. When Sp_{O_2} decreases rapidly, changing the LAL from 90% to 85% delays the onset of the alarm only marginally. None the less, the incidence of desaturation less than 85% was higher in group 85. As can be seen in table 3 the speed of desaturation was more gradual in those patients who became hypoxaemic for more than 1 min in group 85. The interval$^{90–85\%}$ appears to be a crucial period in the institution of therapy to prevent prolonged hypoxaemia when desaturation is more gradual. This suggests that an early alarm is more effective in preventing longer and more severe desaturations than an alarm that sounds when Sp_{O_2} has decreased to less than 85%.

A high frequency of false alarms could be a legitimate argument to reduce the LAL with the aim of increasing specificity. Unfortunately, many technical problems (dislocation of the sensor, peripheral vasoconstriction, patient movement) produce artefactual rapid Sp_{O_2} decreases to values of 80–90%.[14] Previous studies have shown that as many as 50% of pulse oximeter alarms may be false.[3 4 15 16] In group 90 an average of one artefact per patient was present and 30% of the total number of alarms were false. We cannot exclude the possibility that, despite our artefact rejection algorithm and inspection of individual Sp_{O_2} data, several artefacts remained undetected. However, the majority of episodes with Sp_{O_2} $\leqslant$90% were transients which were excluded from calculations of hypoxaemia by the requirement of a minimum duration of 1 min. The criterion of longer than 1 min duration appears to be a valid cut-off point for the detection of true desaturation. Stausholm and colleagues found that 95% of low Sp_{O_2} episodes for more than 1 min were reflected in decreases of transcutaneous oxygen tension measurements.[17] Recent improvements in signal extraction technology may decrease the impact of motion artefact on the quality of the pulse oximeter signal and reduce the frequency of artefacts even further.[18 19] Monitors with a low frequency of false alarms should increase the acceptance by recovery personnel of a higher LAL setting.

Most manufacturers of pulse oximeters give the user the option to average several beats to prevent jitter of the display and unnecessary triggering of the alarm by transients. The benefit of averaging a larger number of beats is the reduction of random variability and diminished susceptibility to transients. As a consequence there is a temporal delay between actual and displayed Sp_{O_2} and delayed triggering of the alarm. Introducing a time delay between the detection of a low Sp_{O_2} and triggering of the audible alarm is an alternative way of reducing the frequency of alarms. Makivirta and Koski found that doubling the pre-alarm delay from 5 to 10 s reduced the mean alarm rate by 26%.[20] In our study a time delay of 15 s between the occurrence of the alarm condition and triggering of the audible alarm would have provided a similar reduction in the number of alarms as a decrease of the LAL from 90% to 85%. One advantage of introducing a time delay as opposed to lowering the LAL could be that hypoxaemia is detected earlier in patients whose Sp_{O_2} decreases more gradually. For example, in group 85, for 27 of the 40 desaturations ($\leqslant$85%, $\geqslant$1 min) the alarm would have been triggered earlier if an LAL of 90% and a 15 s delay of the alarm had been used. A second advantage might be improved attention to longer lasting episodes of mild hypoxaemia with Sp_{O_2} values of 85–90%. In contrast, an alarm delay might result in later detection of severe hypoxaemia if the rate of desaturation is very fast. Because the majority of desaturations had an interval$^{90–85\%}$ of less than 20 s, detection of hypoxaemia and institution of appropriate treatment would have been delayed by several seconds. This potential negative effect would have to balanced against the advantage of having a more specific alarm as a result of elimination of the majority of false alarms.

Uncertainty concerning the optimal LAL has to be acknowledged. To estimate the best cut-off point for a specific test a receiver operator characteristic curve (ROC) is often used.[21] This curve visualizes the trade-off between sensitivity and specificity. The sensitivity and specificity of individual Sp_{O_2} data points can be assessed (for example, by comparison with co-oximetry of arterial blood samples). However, it is impossible to calculate "sensitivity" or "specificity" for a postoperative pulse oximeter monitoring session. The number of false negative episodes (hypoxaemia present, no Sp_{O_2} alarm) is unknown and it is illogical to count the number of true negative episodes (no hypoxaemia, no alarm) because, by definition, each alarm is preceded by a true negative episode. The only variable that we could calculate with some confidence (based on the rejection algorithm) was the positive predictive value (number of true alarms divided by the total number of alarms). The positive predictive value was approximately 70% in both groups although the frequency of alarms was three-fold higher in group 90. Therefore, this value cannot be used to determine the optimal LAL.

In conclusion, the results suggest that recovery room personnel rely on Sp_{O_2} alarms to identify and treat hypoxaemia rather than observation of the patient and the pulse oximeter Sp_{O_2} display. Decreasing the alarm limit in an attempt to reduce frequent false alarms may lead to an increase in clinically relevant hypoxaemia. Maintaining the LAL at 90% and instituting a 15 s time delay before triggering the audible alarm is an equally effective approach to reduce the frequency of alarms that might not hamper rapid detection of hypoxaemia.

Does nitrous oxide antagonize sevoflurane-induced hypnosis?

T. KATOH, K. IKEDA AND H. BITO

Summary

We have studied 64 ASA I and II patients (aged 20–60 yr) to determine if nitrous oxide affects sevoflurane requirements for achieving 50% probability of no movement in response to verbal commands (MAC$_{awake}$). Patients were allocated randomly to one of four nitrous oxide concentration groups (0, 20, 40 and 60 vol.%). Patients in each group received sevoflurane at two different end-tidal concentrations according to a predetermined randomization table. After steady state sevoflurane and nitrous oxide concentrations had been maintained for at least 15 min, patients were assessed as being awake or asleep. The MAC$_{awake}$ for sevoflurane was 0.63% and this was reduced significantly in a non-linear manner by increasing nitrous oxide concentration. A 50% reduction in MAC$_{awake}$ was produced by a nitrous oxide concentration of 45%. The reduction in MAC$_{awake}$ by nitrous oxide was non-linear; the interaction coefficient between nitrous oxide and sevoflurane being significantly less than zero (P=0.0238), indicating that the reduction in MAC$_{awake}$ by nitrous oxide was smaller than would be expected from simple additivity and that nitrous oxide antagonized the effects of sevoflurane in preventing response to verbal commands. (*Br. J. Anaesth.* 1997; **79**: 465–468).

Key words

Anaesthetics volatile, sevoflurane. Anaesthetics gases, nitrous oxide. Potency, anaesthetic, MAC.

End-tidal anaesthetic concentration at the first response to command and the concentration just preventing the response is defined as MAC$_{awake}$.[1] In some studies,[2 3] MAC$_{awake}$ values for isoflurane and sevoflurane were reported to be approximately one-third of MAC values, being different from those of halothane.[4] These MAC$_{awake}$ values were determined when anaesthetics were administered in combination and no other inhaled anaesthetic was used. Nitrous oxide is frequently combined with inhalation anaesthetics and its MAC$_{awake}$ value has been reported to be 0.64 MAC.[5] The drug interaction between nitrous oxide and volatile anaesthetic on awakening concentration is not known well, while nitrous oxide reduced halothane, enflurane, isoflurane and sevoflurane MAC values in a linear manner when added to each respective anaesthetic.[6–9] The purpose of this study was to determine the drug interaction between nitrous oxide and sevoflurane with regard to MAC$_{awake}$ values. We determined which, if any, of three different nitrous oxide concentrations (20, 40 and 60 vol.%) changed the MAC$_{awake}$ value in adult patients. Using the sevoflurane MAC$_{awake}$ determinations in the presence of nitrous oxide, the relationship between nitrous oxide and these volatile anaesthetic MAC$_{awake}$ fractions was determined.

Patients and methods

After obtaining approval from the departmental Ethics Committee and informed consent, we studied 64 patients of both sexes, ASA I and II, aged 20–60 yr, who were undergoing elective surgery. Exclusion criteria were a history of cardiac, pulmonary or renal disease; history of hearing disturbance or ear disease; history of oesophageal reflux or hiatus hernia; drug or alcohol abuse, or significant obesity (body mass index >30); and contraindications to inhalation induction. Patients were fasted for at least 8 h before surgery, were monitored in a routine manner and received no premedication.

The 64 patients were allocated randomly to one of four groups. Patients in group 1 received no nitrous oxide, while those in groups 2, 3 and 4 received end-tidal concentrations of 20, 40 and 60 vol.%, respectively. End-tidal sevoflurane concentrations were chosen to provide both adequate and inadequate anaesthesia at each nitrous oxide concentration, and were based on data from our previous MAC$_{awake}$ studies,[2 3] and the study of Dwyer and colleagues.[5] All patients received sevoflurane at two different concentrations. The inspired concentration of sevoflurane was adjusted to maintain the measured end-tidal concentration constant at the value predetermined according to a randomization scheme (fig. 1).

After an anaesthesia face mask was placed on the face of patients using a head strap, we confirmed that air leak from the margin of the mask was minimal when positive or negative airway pressure was applied to the inside of the mask. The mandible was displaced upward gently with two hands to avoid the

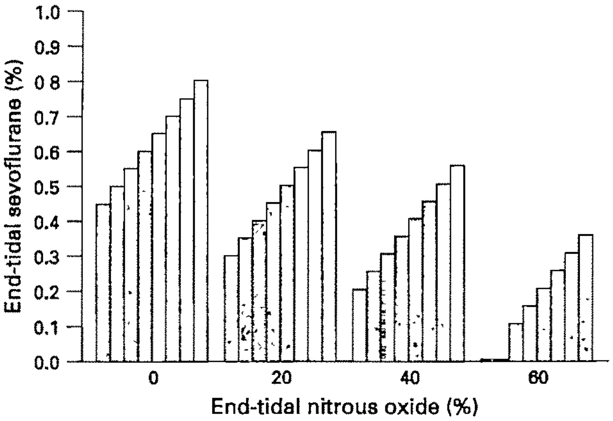

Figure 1 Assessment of loss of response to verbal command: end-tidal sevoflurane concentrations for each patient in each of the nitrous oxide concentration groups. Each bar represents four patients.

upper airway obstruction that may occur in unconscious patients. All patients breathed through the mask connected to a semi-closed anaesthetic system. To prevent contamination of end-tidal samples with inspired gas, the deadspace was augmented at the sampling port. Gas was withdrawn continuously from the sampling port, located between the face mask and deadspace, at a rate of 200 ml min^{-1}. Concentrations of nitrous oxide, carbon dioxide, sevoflurane and oxygen were measured continuously using an infrared anaesthetic gas analyser (Capnomac Ultima, Helsinki, Finland) which was calibrated before anaesthesia for each patient using a standard gas mixture. Patients breathed spontaneously, and ventilation was assisted if tidal volume was too small to provide adequate end-tidal sampling for measurement of anaesthetic concentration. Staff in the operating theatre were instructed to be quiet and not to physically stimulate the patient. Patients were instructed not to open their eyes, talk or move before a verbal command.

After steady state nitrous oxide and sevoflurane concentrations had been maintained for at least 15 min, patients were assessed as being awake or asleep by having their name called out in a normal tone and by being instructed to open their eyes. The patient's response to the verbal command was recorded as positive or negative, with slight movement of the eyelids considered a negative response.

STATISTICAL ANALYSIS

The $\text{MAC}_{\text{awake}}$ of sevoflurane and its reduction by nitrous oxide was evaluated using the following multiple independent variable logistic regression model:

$$P\,(\text{no response}) = \frac{1}{1+e^{-Z}}$$

$$Z = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_{12} X_1 X_2$$

where X_1=end-tidal sevoflurane concentration, X_2=end-tidal nitrous oxide concentration, β_0=regression intercept constant, β_1=coefficient for sevoflurane, β_2=coefficient for nitrous oxide and β_{12}=coefficient for the product of the end-tidal sevoflurane and nitrous oxide concentrations (interaction coefficient). The likelihood ratio test was applied to determine the independent variables to be removed from the model. The $\text{MAC}_{\text{awake}}$ for a given end-tidal nitrous oxide concentration was determined by setting the probability of no response to 0.5 and solving for sevoflurane concentration as a function of end-tidal nitrous oxide concentration as follows:

$$X_1 = \frac{-(\beta_0 + \beta_2 X_2)}{\beta_1 + \beta_{12} X_2} \qquad (1)$$

The concentration of sevoflurane required to prevent response in 95% of patients ($\text{MAC}_{\text{awake95}}$) was also determined from each model by setting the probability of no movement to 0.95 and solving for sevoflurane concentration. The responses of patients to verbal command at each nitrous oxide concentration were subjected to probit analysis, in order to determine $\text{MAC}_{\text{awake}}$ and its 95% confidence limits. These statistical analysis was performed using SPSS software (SPSS, Inc., Chicago, IL, USA).

Results

Although a total of 64 patients were enrolled in the study, we could not assess eight responses in six patients because of pronounced excitatory phenomena and vomiting. Thus the results for 120 assessments in 58 patients are presented. This group included 27 men and 31 women with a mean age of

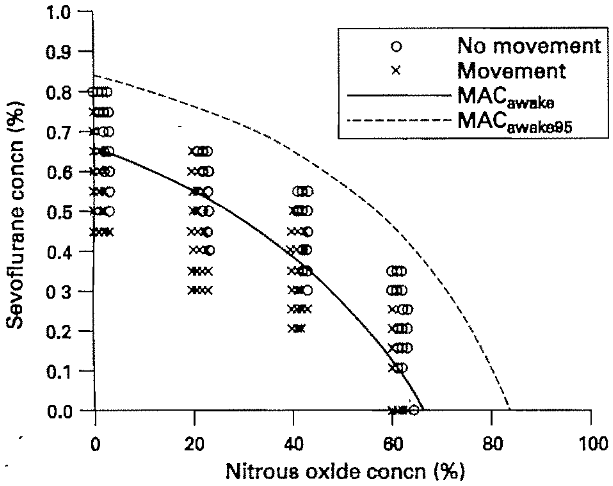

Figure 3 Reduction of sevoflurane concentration, by increasing concentrations of nitrous oxide, at which 50% (MAC$_{awake}$) or 95% (MAC$_{awake95}$) of patients did not respond to verbal commands.

47.5 yr (range 20–60 yr) and a mean body weight of 54.2 kg (40–81 kg).

The logistic model was fitted to 120 data sets of observed responses, end-tidal sevoflurane concentrations and end-tidal nitrous oxide concentrations. Coefficient estimates for the logistic regression model are presented in table 1. None of the three independent variables was removed from the model based on the likelihood ratio test. The interaction coefficient β_{12} was significantly less than zero (P=0.0238). The MAC$_{awake}$ and MAC$_{awake95}$ of sevoflurane in the absence of nitrous oxide were 0.63 and 0.93%, respectively. The probability of no movement in response to verbal command *vs* end-tidal sevoflurane concentration in the absence or presence of nitrous oxide is presented in figure 2. Reduction in the MAC$_{awake}$ of sevoflurane by nitrous oxide is presented in figure 3. MAC$_{awake}$ of nitrous oxide calculated as nitrous oxide concentration which would reduce MAC$_{awake}$ of sevoflurane to 0%, was 66%. A 50% reduction in MAC$_{awake}$ of sevoflurane was produced by a nitrous oxide concentration of 45%.

Discussion

The effect of nitrous oxide on the MAC$_{awake}$ value of sevoflurane has not been documented previously. Nitrous oxide, however, has been shown to reduce the MAC$_{awake}$ for isoflurane in a dose-dependent manner, with the MAC$_{awake}$ reported as 67%.[4] Thus 20, 40 and 60% nitrous oxide should correspond to MAC$_{awake}$ fractions of 0.3, 0.6 and 0.9, respectively. Chortkoff, Bennett and Eger examined the ED$_{50}$ for suppression of learning and ability to respond appropriately to verbal commands using the combination of isoflurane with 40% nitrous oxide. For both ED$_{50}$ values, a slightly higher value was reported than predicted by the assumption of additivity.[10] This indicates that the two anaesthetics are antagonistic with regard to this hypnotic effect. We found that nitrous oxide reduced the MAC$_{awake}$ of sevoflurane in a dose-related manner. The interaction coefficient between sevoflurane and nitrous oxide was significantly less than zero, indicating that nitrous oxide had a non-linear effect on reducing sevoflurane requirements and that sevoflurane requirements were greater than would be expected from simple additivity.

The results of this study showed that 33% nitrous oxide would reduce the MAC$_{awake}$ of sevoflurane to 68.1%, and that the sevoflurane MAC$_{awake}$ value is 18% greater than the value expected from simple additivity of the two agents. These findings correspond to those reported with isoflurane.[10] Nitrous oxide appears to antagonize the effect of sevoflurane to prevent responses to verbal commands. Nitrous oxide has some characteristics of a central nervous system stimulant.[11–13] It fails to supplement isoflurane-induced depression of cerebral metabolic rate[14] and may antagonize the electroencephalographic effects of volatile agents.[15] A study by Yli-Hankala and colleagues showed that the addition of nitrous oxide to isoflurane decreased the frequency and duration of isoflurane-induced burst suppressions in the electroencephalogram in an apparently non-additive interaction.[16] Although we did not monitor the EEG in this study, this activating mechanism may explain our findings.

We reported that nitrous oxide produced a non-liner reduction in thiopentone requirements for preventing response to verbal commands.[17] The findings of this study agree with those of our previous study. The observed deviation from linearity of the interaction between nitrous oxide and sevoflurane was rather small, so that clinical relevance may be questioned.

It has been shown that the interaction between nitrous oxide and volatile agents such as halothane, enflurane or isoflurane is additive in the sense that the linear combination of two MAC fractions of nitrous oxide and the volatile agent equating to 1.0 MAC also prevents response to skin incision in 50% of patients. We reported that the MAC of sevoflurane was also reduced by nitrous oxide in an additive manner.[9] Recent studies by Cole and colleagues claimed to have shown a non-linear contribution to the interaction of nitrous oxide with halothane, enflurane and isoflurane in rats.[18 19] Gauman, Mustaki and Tassonyi demonstrated that ratios of MAC$_{awake}$ to MAC differed for the anaesthetics halothane, enflurane and isoflurane in humans.[4] Their findings do not support a unitary mechanism of anaesthetic action. Instead, response to noxious stimuli such as skin incision and response to verbal command seem to be depressed by different mechanisms. Although nitrous oxide has an additive effect with these volatile agents in preventing movement in response to surgical incision, this may not translate to additivity for suppression of responsiveness to a verbal command.

In our study we demonstrated that nitrous oxide had a non-linear effect on reducing sevoflurane, and the shape of the reduction curves in MAC$_{awake}$ by nitrous oxide differed from that in MAC. In rats, acute decerebration (removal of part of the central nervous system—cortex and thalamus) did not affect the concentration of isoflurane required to prevent movement in response to tail-clamping.[20] In goats with the brain preferentially anaesthetized, higher anaesthetic concentrations were required to prevent movement in response to a clamp; this supports the importance of subcortical structures, such as the spinal cord, in the generation of purposeful movement in response to a painful stimulus under general anaesthesia.[21] These observations suggest that motor responses in response to a noxious stimulus may be mediated primarily by subcortical structures, including the spinal cord, at least in lower animals. In contrast, purposeful responsiveness to a verbal command apparently requires intact cortex function. Different end-points (no response to verbal command *vs* no response to noxious stimulus) may be associated with different sites of anaesthetic action.[22] Therefore, the type and degree of interaction between any two anaesthetics may depend on the clinical end-point used.

We calculated the $\text{MAC}_{\text{awake}}$ of nitrous oxide as the concentration of nitrous oxide which would reduce the $\text{MAC}_{\text{awake}}$ of sevoflurane to 0% by extrapolating equation (1). The predicted $\text{MAC}_{\text{awake}}$ value (66%) was almost equal to that determined by Dwyer and colleagues.[5] Nitrous oxide alone did not reliably prevent conscious awareness during anaesthesia. The probability of no movement in response to verbal command *vs* end-tidal sevoflurane concentration in the presence of 60% nitrous oxide revealed that nitrous oxide would prevent 20% of patients from responding to verbal commands at this nitrous oxide concentration in the absence of sevoflurane (fig. 2). Dwyer and colleagues reported that the percentage of volunteers not responding purposefully to verbal commands at 0.6 MAC (62%) of nitrous oxide was 20%.[5]

In conclusion, we have studied the interaction between nitrous oxide and sevoflurane on loss of consciousness. The $\text{MAC}_{\text{awake}}$ of sevoflurane was 0.63% and this was reduced significantly in a non-linear manner by increasing nitrous oxide concentration. A 50% reduction in the $\text{MAC}_{\text{awake}}$ value was produced by a nitrous oxide concentration of 45%. The reduction in $\text{MAC}_{\text{awake}}$ by nitrous oxide was less than would be expected from simple additivity at low concentrations.

Effect of incremental doses of sevoflurane on cerebral pressure autoregulation in humans

S. GUPTA, K. HEATH AND B. F. MATTA

Summary

We have examined cerebral pressure autoregulation while awake, and during 0.5 and 1.5 MAC of sevoflurane anaesthesia in 10 patients undergoing non-intracranial neurosurgical procedures. All patients received a standardized anaesthetic comprising premedication with temazepam 20 mg orally, a sleep dose of propofol, fentanyl 1 μg kg^{-1} and vecuronium 0.1 mg kg^{-1}. After tracheal intubation, the lungs were ventilated with a mixture of air and oxygen to mild hypocapnia. Routine monitors included ECG, continuous and intermittent non-invasive arterial pressure, pulse oximetry and end-tidal capnography. In addition, blood flow velocity (vmca) was measured by insonating the middle cerebral artery transtemporally using a 2-MHz transcranial Doppler probe. Cerebral pressure autoregulation was tested by increasing mean arterial pressure (MAP) by approximately 20 mm Hg using an infusion of phenylephrine and simultaneously recording vmca. The index of autoregulation (IOR) during each period of the study, calculated as the ratio of percentage change in estimated cerebral vascular resistance (CVRe=MAP/vmca) to percentage change in MAP, was compared using ANOVA. vmca during 0.5 and 1.5 MAC of sevoflurane anaesthesia was significantly lower than that while awake (mean 79 (SD 24), 54 (15) and 51 (12) cm s^{-1}, respectively; $P<0.05$). There was no significant change in vmca with the increase in MAP while awake, or during 0.5 or 1.5 MAC of sevoflurane anaesthesia and IOR was similar under the three conditions (0.82 (0.11), 0.83 (0.04) and 1.0 (0.03), respectively). We conclude that cerebral pressure autoregulation remained intact during sevoflurane anaesthesia in humans. (*Br. J. Anaesth.* 1997; **79**: 469–472).

Key words
Anaesthetics volatile, sevoflurane. Brain, blood flow. Measurement techniques, Doppler ultrasonography.

Cerebral pressure autoregulation, a sensitive mechanism impaired in a dose-dependent manner by inhaled anaesthetics, minimizes changes in cerebral blood flow (CBF) when cerebral perfusion pressure changes.[1–4] This study was designed to investigate the effects of incremental doses of the recently introduced inhalation anaesthetic, sevoflurane, on cerebral pressure autoregulation in humans.

Patients and methods

After obtaining local Ethics Committee approval and written informed consent, we studied 10 ASA I or II patients, aged 25–66 yr (mean 48 yr), weighing 52–90 kg (mean 72 kg), undergoing non-intracranial neurosurgical procedures. Patients with neurological, respiratory or cardiovascular disease and those receiving psychotropic drugs were excluded. Patients less than 18 yr of age were also excluded. Routine monitors included ECG, continuous and intermittent non-invasive arterial pressure (Finapress and Dinamap, Ohmeda, USA), pulse oximetry and capnography. In addition, a 2-MHz transcranial Doppler ultrasound probe (DWL Multidop, Sipplingen, Germany) was used to measure the time-averaged mean flow velocity (*v*mca) in the middle cerebral artery (MCA). The probe was secured in position in a specially designed frame after using standard criteria to obtain the best signal possible from the vessel at a depth of 45–55 mm.[5] All patients received a standard anaesthetic comprising premedication with temazepam 20 mg orally, propofol 2–2.5 mg kg^{-1}, fentanyl 1 μg kg^{-1} and vecuronium 0.1 mg kg^{-1}, and their lungs were ventilated with a mixture of air and oxygen ($F_{I_{O_2}}$ 0.35) to maintain mild hypocapnia. Body temperature was maintained greater than 36 °C in all patients using warmed i.v. fluids and a warming blanket. Repeated doses of vecuronium were used to maintain neuromuscular block as required. When necessary, an infusion of phenylephrine was used to maintain mean MAP as close as possible to baseline.

AUTOREGULATION TESTING

Cerebral pressure autoregulation was examined three times in each patient: while awake, during 0.5 and 1.5 MAC of sevoflurane anaesthesia (after

Table 1 Mean (SD) data during pressure autoregulation testing. *$P<0.05$ compared with awake; †$P<0.05$ compared with baseline (ANOVA)

	Awake	0.5 MAC sevoflurane	1.5 MAC sevoflurane
End-tidal CO_2 (kPa)	5.1 (0.6)	4.5 (0.6)	4.5 (0.5)
Baseline *v*mca (cm s^{-1})	79 (24)	54 (15)*	51 (12)*
Autoregulation *v*mca (cm s^{-1})	82 (23)	56 (11)*	51 (12)*
Baseline heart rate (beat min^{-1})	81 (15)	77 (15)	63 (12)
Autoregulation heart rate (beat min^{-1})	60 (12)†	65 (15)†	52 (7)†
Baseline MAP (mm Hg)	95 (10)	86 (12)	85 (13)
Autoregulation MAP (mm Hg)	117 (10)†	109 (14)†	106 (15)†
Change in MAP (mm Hg)	22 (6)	23 (4)	22 (3)
IOR	0.82 (0.11)	0.83 (0.04)	1.0 (0.03)

15 min of unchanged end-tidal concentration and before the start of surgery). Autoregulation was tested by inducing an increase in MAP of approximately 20 mm Hg using an infusion of 0.01% phenylephrine and simultaneously recording *v*mca. *v*mca and MAP were used for subsequent calculation of the estimated cerebral vascular resistance (CVRe=MAP/*v*mca) at each stage.

The index of autoregulation (IOR), defined as the ratio of percentage change in estimated CVRe to percentage change in MAP, was calculated for each period of the study.[6] Theoretically, no change in *v*mca should occur if the percentage change in CVRe is equal to the percentage change in MAP. Thus an IOR of 1 implies perfect autoregulation and an IOR of 0, complete disruption of autoregulation. Based on previously published autoregulation data in humans, we considered a change less than 15% in IOR to be clinically insignificant.[7] Power analysis showed that for a power of 0.8, an alpha error of 0.05 and a beta error of 0.20, the required number of patients to reject the null hypothesis was 10. The computed IOR, and data recorded before and after the phenylephrine-induced increase in MAP, were analysed using ANOVA. $P<0.05$ was considered significant.

Results

The major findings of the study are shown in table 1. There was no significant change in patient body temperature, arterial saturation or end-tidal carbon dioxide. Mean *v*mca was significantly lower during 0.5 and 1.5 MAC of sevoflurane anaesthesia (79 (SD 24), 54 (15) and 51 (12) cm s^{-1}, respectively) ($P<0.05$).

Baseline MAP, heart rate and the phenylephrine-induced increase in MAP were similar during the three periods of the study. The phenylephrine-induced increase in MAP did not cause a significant change in *v*mca while awake, or at 0.5 or 1.5 MAC of sevoflurane anaesthesia. Hence, the calculated IOR values were similar during the three periods of the study (0.82 (0.11), 0.83 (0.04) and 1.0 (0.03), respectively).

Discussion

We have shown that sevoflurane did not affect cerebral pressure autoregulation in humans. This is in contrast with other commonly used inhalation agents which abolish autoregulation in a dose-dependent manner.[3] Therefore, a degree of healthy criticism is warranted in order to provide a reasonable explanation for our findings.

Carbon dioxide is a potent cerebral vasodilator. Hypercapnia exhausts the cerebral vasodilator response to changes in perfusion pressure thus reducing autoregulatory capacity.[8] In contrast, hypocapnia increases cerebral vascular tone resulting in improved cerebral autoregulation.[9] The end-tidal carbon dioxide concentration during the course of the study remained relatively unchanged at just less than 5 kPa and is unlikely to have significantly influenced the autoregulatory mechanism.

The other drugs used during the study do not have direct cerebrovascular effects. Propofol was used for induction of anaesthesia and most of the induction dose would have undergone re-distribution before autoregulation testing during sevoflurane anaesthesia was commenced. Fentanyl and vecuronium have no direct cerebral vasodilator effects and do not affect cerebral autoregulation.[10 11]

We used transcranial Doppler ultrasonography (TCD), a non-invasive inexpensive device, as a measure of CBF. Although TCD does not provide a direct measure of CBF, provided the angle of insonation and the diameter of the vessel insonated remain constant, changes in *v*mca accurately reflect relative changes in CBF.[12–14] We used a frame designed specially to maintain the probe in position, thus ensuring that the angle of insonation remained constant throughout the study. There is also now ample direct and indirect evidence to support the view that the diameter of the MCA does not change significantly with changes in arterial pressure, Pa_{CO_2} or the use of anaesthetic or vasoactive agents.[13–18]

As we measured *v*mca and not absolute CBF, we could only estimate cerebral vascular resistance (CVRe). We then calculated the index of autoregulation by dividing the percentage change in CVRe by the percentage change in MAP. This method has been used before as a measure of cerebral autoregulatory capacity.[3 6] As reported previously, an IOR of 1 indicates that the percentage change in CVRe is the same as the percentage change in MAP and no change in CBF results; perfect autoregulation. Complete absence of autoregulation gives an IOR of 0. The calculated IOR values during 0.5 and 1.5 MAC of sevoflurane anaesthesia were similar to awake values, indicating that cerebral autoregulation remained intact during sevoflurane anaesthesia in humans. Power analysis ensured that 10 patients were sufficient to reject the null hypothesis with a power of 0.80, an alpha error of 0.05 and a beta error of 0.20, assuming a change less than 15% in the IOR to be clinically insignificant.[7]

Although we examined autoregulation in only one direction (increase in pressure), we chose a level of MAP in the middle of the autoregulation curve. Therefore, there is no reason to assume that a decrease instead of an increase in MAP would have yielded different results. This has been confirmed recently by Tiecks and colleagues who found that the ability of the cerebral circulation to autoregulate was similar if MAP was increased or decreased.[19]

We chose to examine the effects of 0.5 and 1.5 MAC of sevoflurane on cerebral pressure autoregulation to allow comparison with published data on other inhalation agents. For example, both isoflurane and desflurane abolish autoregulation at 1.5 MAC.[3] Furthermore, it is unlikely that an inhalation agent may be used in neuroanaesthetic practice at concentrations greater than 1.5 MAC.

Our findings are in agreement with the recently published reports on cerebral autoregulation during sevoflurane anaesthesia. Hanel and colleagues have shown that cerebral pressure autoregulation is maintained during 0.5 and 2.0 MAC of sevoflurane anaesthesia in pigs.[20] Kitaguchi and colleagues demonstrated that cerebral pressure autoregulation is maintained during 0.88 MAC of sevoflurane anaesthesia in patients with ischaemic cerebrovascular disease undergoing extracranial intracranial bypass.[21] Cho and co-workers also reported that cerebral pressure autoregulation was maintained during 1.2 MAC of sevoflurane anaesthesia or a mixture of 1.2 MAC of sevoflurane with 60% nitrous oxide in six patients.[22] Why should sevoflurane, an agent similar to isoflurane in many of its systemic effects, have a significantly different effect on cerebral autoregulation?

It is generally accepted that the effect of inhalation anaesthetics on the cerebral vasculature is dependent on the balance between their direct cerebral vasodilator action and the indirect vasoconstrictive effect consequent upon normal flow–metabolism coupling.[23] Thus the net effect on CBF of adding an inhalation agent depends on the level of cerebral metabolism before the agent is added. When cerebral metabolism is already depressed, the agent increases CBF by vasodilatation of cerebral vessels. However, if the agent is administered to patients who are in a "light plane of anaesthesia" or awake, its cerebral metabolic depressant effect leads to a decrease in CBF. Hence, while at lower concentrations the major effect on CBF is vasoconstrictive secondary to flow–metabolism coupling, at higher concentrations the direct vasodilator effect predominates with increases in CBF and loss of cerebral autoregulation.[24] From recently published data and from work carried out at our institution, it would appear that sevoflurane has a less direct vasodilator effect than either isoflurane or desflurane.[25 26] Furthermore, work carried out in this institution suggests that the direct vasodilator effect of sevoflurane at 1.5 MAC is approximately 30% of the effect with isoflurane.[26] This explains maintenance of autoregulation at 1.5 MAC, as the major effect is vasoconstriction secondary to flow–metabolism coupling. Hence the cerebral vasculature remains capable of responding to changes in perfusion pressure. Indeed, *v*mca values at 0.5 and 1.5 MAC are in agreement with this hypothesis.

We conclude that cerebral pressure autoregulation was preserved during 0.5 and 1.5 MAC of sevoflurane anaesthesia in humans. This is advantageous for an agent that has many properties favouring its use in neuroanaesthetic practice.

Comparison of isoflurane with propofol on respiratory cilia

J. H. RAPHAEL AND M. W. BUTT

Summary

We have investigated the effects of two techniques of clinical anaesthesia on human respiratory cilia by measuring cilia beat frequency of nasal tissue. In a randomized, controlled study, 13 patients undergoing either inhalation anaesthesia with isoflurane or total i.v. anaesthesia with propofol and alfentanil had nasal ciliated epithelial samples removed at the beginning and after 1 h of anaesthesia. Mean cilia beat frequency in the group anaesthetized with isoflurane changed significantly from 11.5 (95% confidence interval (CI) 10.7–12.2) Hz to 9.1 (8.1–10.1) Hz after anaesthesia whereas in the group anaesthetized with propofol and alfentanil there was a change from 11.5 (10.7–12.2) Hz to 11.0 (10.2–11.8) Hz (ns). The difference between the anaesthetic agents on cilia beat frequency was significant (MANOVA, $P<0.01$). These data suggest that different anaesthetic agents may impair respiratory defence mechanisms to differing extents. (*Br. J. Anaesth.* 1997; **79**: 473–475).

Key words

Lung, trachea. Lung, mucus. Anaesthetics i.v., propofol. Anaesthetics volatile, isoflurane.

Advances in anaesthesia over the past few decades have produced a very low level of mortality associated with anaesthesia; a recent report found that only three deaths out of almost 0.5 million procedures resulted from anaesthesia alone.[1] Consequently, greater attention has focused on morbidity associated with anaesthesia, especially on serious forms of morbidity. An important and common type of morbidity is that caused by pulmonary infection. Prospective studies have described an incidence of 6–21%.[2–5]

The causes of postoperative pulmonary infections are multifactorial but depend on clearance of lung secretions. This requires effective coughing and ciliary transport of respiratory mucus. Most attention has been directed at improving coughing after its impairment by the effects of both anaesthesia and surgery. However, although it has been known for some time that anaesthetic agents can impair mucus transport rates,[6 7] there have been few investigations.

It is most likely that impairment of mucus transport is caused by effects of the anaesthetic agents on the cilia.[8] The most important determinant of ciliary transport of mucus is ciliary beat frequency[9] and we have demonstrated previously, *in vitro*, differential effects of anaesthetic agents on cilia with a depressant effect after inhalation agents but no effect with propofol.[10 11] This raises the possibility of a difference in clinical practice between the two techniques of inhalation anaesthesia and total i.v. anaesthesia (TIVA).

To investigate this possibility further, we have conducted a double-blind, randomized, controlled study of the effects of these two anaesthetic techniques on human respiratory cilia beat frequency.

Patients and methods

After obtaining Ethics Committee approval and informed patient consent, we studied 13 patients (nine males, four females, aged 27–71 yr) undergoing elective peripheral body surgery under general anaesthesia. Anaesthesia was induced with fentanyl 50–125 μg and propofol 160–320 mg, and a sample of ciliated nasal epithelial cells was obtained by passing a bronchoscopy brush over the inferior nasal turbinates as described previously.[12] The brush was agitated in M199 medium to remove the cells.

Patients were allocated randomly to maintenance of anaesthesia with either an inhalation anaesthetic agent or TIVA as follows. Anaesthesia was maintained by face mask anaesthesia with 30–45% oxygen in air flowing via a circle system at 3 litre min^{-1} with the addition of either isoflurane or an i.v. infusion of propofol and alfentanil. Propofol and alfentanil were mixed together in a 60-ml syringe containing propofol 60 ml and alfentanil 2 mg. The concentration of isoflurane and the rate of propofol–alfentanil infusion were determined by clinical response to surgery. All patients received ketorolac 15 mg i.m. and local anaesthetic infiltration or regional nerve block of the surgical field before commencement of surgery.

The following variables were monitored and recorded: fractional inspired oxygen concentration, end-tidal carbon dioxide concentration, oesophageal temperature, non-invasive arterial pressure, ECG, arterial oxygen saturation and end-tidal isoflurane concentration.

J. H. RAPHAEL, MD, FRCA, M. W. BUTT, MB, BS, BA, FRCA, University Department of Anaesthesia, Leicester Royal Infirmary, Leicester LE1 5WW. Accepted for publication: May 28, 1997.

After 1 h of anaesthesia a second sample of nasal ciliated epithelium was obtained in the same manner as before.

Measurement of cilia beat frequency was undertaken as described and validated previously.[13] Within 5 min of removal from the patient, the ciliated samples were transferred to a heated chamber for viewing by differential interference contrast microscopy (Nikon Diaphot 200, Nikon UK). The image of the cilia was transmitted to a video monitor (Sony KX-14CPI) via a video camera (Panasonic vw-CL 1 1 0-AK) to provide a magnified image of the moving cilia of 3000×. A pinhead photodiode with a diameter of 1 mm^2 was attached to the monitoring screen to detect interference in light caused by the moving cilia. The voltage across the diode was amplified to provide a signal to an oscilloscope greater than 0.2 V and low pass filtered with a cut-off above 25 Hz. The changing voltage signals were sampled by an analogue-to-digital converter. The voltage signals were collected over a period of 15 s and divided into three sequential 5-s intervals for analysis. Data were analysed by software written in Mathematica 2.2 to provide a power spectrum using fast Fourier transforms. The peak of the power spectrum was taken to represent cilia beat frequency. Acceptable ciliated edges for measurement were defined as those devoid of mucus and at least 60 µm in length. Measurements were not taken from individual cells or disrupted edges. Eight areas of continuous ciliated epithelium were measured from each sample of ciliated tissue. The peaks of the power spectra were analysed by MANOVA applied to the differences between the treatment groups with significance taken at $P<0.05$.

Results

Six patients were allocated randomly to receive isoflurane and seven to receive TIVA. Patients underwent lower limb varicose vein operations or day-case limb orthopaedic procedures. The groups were similar in age, sex distribution, oxygen saturation, carbon dioxide tension and core temperature (table 1). The range of end-tidal isoflurane concentrations measured was 1.5–2.5% and the range of propofol delivered was 500–600 mg. Mean cilia beat frequency in the group anaesthetized with isoflurane changed from 11.5 (95% confidence interval (CI) 10.7–12.2) Hz to 9.1 (8.1–10.1) Hz after anaesthesia and in the group anaesthetized with propofol and alfentanil from 11.5 (10.7–12.2) Hz to 11.0 (10.2–11.8) Hz (fig. 1). The difference between the anaesthetic agents on cilia beat frequency was significant (MANOVA, $P<0.01$).

Table 1 Patient data and variables measured during anaesthesia (mean (95% CI)) in the group who received inhalation anaesthesia (IA) compared with the total i.v. anaesthesia (TIVA) group

	Group IA	Group TIVA
n	6	7
Sex (M/F)	4/2	5/2
Age (range) (yr)	29–38	27–71

Discussion

We have found a difference in the beat frequency of nasal cilia exposed to inhalation agent anaesthesia with isoflurane compared with TIVA with propofol and alfentanil.

The reduction in beat frequency after 1 h of isoflurane anaesthesia was 2.4 Hz. This reduction of more than 20% is significant in terms of its effects on mucus transport. This is based on the logarithmic relationship between cilia beat frequency and mucus transport rate[14] such that modest reductions in beat frequency of the cilia are accompanied by greater reductions in mucus transport rate, and represents approximately a 50% reduction in mucus transport rate.

In previous work we have shown that a bolus dose of propofol has no effect on nasal cilia beat frequency measured 1 h later[13] and in another investigation we showed there were no opioid receptors on the nasal cilia.[15] Therefore, a bolus of propofol and fentanyl would not be expected to have an effect on cilia beat frequency. Baseline cilia beat frequency was similar in the two groups and is in close agreement with that reported previously in awake volunteers.[16]

End-tidal isoflurane concentration were 1.5–2.5%. In our earlier *in vitro* experiments, we found similar reduction of 3 Hz with 2 MAC of isoflurane.[17] In an *in vitro* study of propofol on cilia beat frequency in which 70 µmol litre^{-1} (approximately twice the concentration during TIVA) was perfused over ciliated tissue, we found no change in cilia beat frequency.[11] Thus our *in vitro* investigations concur with the findings from this clinical study.

We undertook a comparative study of patients under anaesthesia because there were several limitations to our earlier *in vitro* investigations. It is likely that the concentrations of drugs in the cilia are different when drugs are delivered to tissue samples in the laboratory compared with delivery by anaesthetic equipment to patients. Indeed the difference between these two agents on the cilia may be the result of different methods of delivery in clinical practice, with gas phase drug delivery possibly being more harmful than delivery to the cilia via the bloodstream. Furthermore, previous *in vitro* work did not include a controlled investigation comparing these two agents.

Various methods have been described for measurement of cilia beat frequency but are limited to *in vitro* techniques. Laser light scattering spectroscopy is a recent and sophisticated light technique that is not restricted to *in vitro* use[18]; however, this technique is invasive and its use has been restricted by its expense which has limited its validation. The *in vitro* transmitted light technique is the most widely used and reliable technique for measurement of cilia beat frequency. It is reproducible, convenient and requires minimal subjective assessment; however, it is subject to the effects of extraneous vibrations and it cannot detect individual cilia. We have overcome the problem of vibration by setting the imaging system on an anti-vibration concrete base.[13] Using an *in vitro* method for determination of cilia beat frequency introduces possible effects on the cilia by removal from their natural environment; however, the experiment was conducted in a controlled manner to take account of this.

It has been demonstrated by other workers that cilia beat frequency measured from nasal brushings is the same as that from samples taken from further down the respiratory tract[19] and therefore nasal samples are likely to be representative of cilia from more distal parts of the lungs. Therefore, we elected to use nasal tissue for analysis as this is a less invasive sampling technique and modified the anaesthetic technique accordingly. By using a face mask, the inhalation anaesthetic agents passed over these ciliated cells in a similar manner to effects on bronchial cilia when using other airway devices.

The effects of a reduction in cilia beat frequency on respiratory defences and the subsequent development of pulmonary infections is not known. Retrospective comparisons of inhalation anaesthesia and TIVA have not demonstrated a difference in this regard.[20] A controlled prospective study is required including groups at risk of postoperative pulmonary infections to determine if the choice of anaesthetic technique is important in this regard.

Platelet function is inhibited by nitric oxide liberation during nitroglycerin-induced hypotension anaesthesia

H. Aoki, M. Inoue, T. Mizobe, M. Harada, H. Imai and A. Kobayashi

Summary

The inhibitory effects of nitroglycerin (NTG) on platelet function and the mechanisms of inhibition have been studied *in vitro*, but not *in vivo*. Therefore, we have investigated the effects of NTG on platelet function in eight patients undergoing orthopaedic surgery. Simultaneous measurements of platelet aggregation and change in intracellular calcium concentrations were performed in Fura-2 loaded platelets using thrombin as a stimulator. Intraplatelet concentrations of cyclic 3′,5′-guanine monophosphate (cGMP) were measured by radioimmunoassay, and the concentration of nitrite ion was also measured. Continuous i.v. infusion of NTG 4–8 μg kg^{-1} min^{-1} significantly inhibited platelet aggregation and the increase in intracellular Ca^{2+} concentration (first phase, mean 439.9 (SEM 68.7) *vs* 210.6 (38.7) nmol litre^{-1}; second phase, 154.4 (19.8) *vs* 106.7 (18.0) nmol litre^{-1}). The concentration of cGMP (from 0.633 (0.098) to 1.764 (0.578) pmol/10^9 platelets) and the concentration of nitrite ion (from 532.6 (17.6) to 724.4 (34.8) nmol litre^{-1}) also increased significantly after infusion of NTG. The NTG concentration in plasma was of the order of 10^{-8} mol litre^{-1}. We have demonstrated that *in vivo*, NTG increased intraplatelet cGMP concentrations and inhibited platelet function; one mechanism of this effect is likely to be related to nitric oxide liberation from NTG bioconversion. (*Br. J. Anaesth.* 1997; **79**: 476–481).

Key words
Anaesthetic techniques, hypotensive. Pharmacology, nitroglycerin. Gases non-anaesthetic, nitric oxide. Blood, platelets. Blood, coagulation.

Organic nitrates, such as nitroglycerin (NTG), have been used widely for the treatment of myocardial infarction and angina pectoris.[1] It has been reported that the major pharmacological action of NTG is vasodilatation of vascular smooth muscle.[2] The effects of NTG on platelets may also represent an important pharmacological effect.[3] The inhibitory effects of NTG on platelet function were first demonstrated by Hampton and colleagues,[4] and have subsequently been reported by many investigators. Prevention of platelet aggregation by several organic nitrates may be effective both prophylactically and therapeutically.[5] However, in studies which demonstrated these effects of NTG *in vitro*, the concentrations used were higher than those pharmacologically attainable *in vivo*.[6–9] In fact, in one *in vivo* study infusion of NTG at approximately 1 μg kg^{-1} min^{-1} failed to demonstrate similar effects of NTG on platelet aggregation.[10] Much higher doses of NTG are given for induced hypotensive anaesthetic techniques during surgery, thus providing an opportunity to study the effects of NTG on platelet function *in vivo* at doses higher than those reported previously.

Patients and methods

This study was approved by our Institutional Committee on Human Research, and informed consent was obtained from all subjects. We studied eight patients (four men and four women) undergoing orthopaedic surgery of the hip joint. Mean age was 50.9 (range 22–75) yr. All patients were ASA I or II, and none had any known haematological abnormalities. Patients being treated with medications that may affect platelet function were excluded.

Patients were premedicated with atropine 0.01 mg kg^{-1} and hydroxyzine 1 mg kg^{-1} i.m. Thirty minutes later, thiopentone 5 mg kg^{-1} was administered i.v. for induction of general anaesthesia, and tracheal intubation was facilitated with vecuronium. Thereafter, anaesthesia was maintained with isoflurane and 66% nitrous oxide in oxygen, using an appropriate dose of vecuronium as a neuromuscular blocking agent. A 20-gauge catheter was inserted into the radial artery to measure arterial pressure and collect arterial blood. While the concentration of isoflurane was kept at 1% and a stable haemodynamic state was maintained, NTG solution (5 mg in 40 ml of saline) was administered i.v. using an infusion pump (Syringe pump, model STC-525, Terumo Co., Tokyo) through an extension tube coated with non-absorbable silicone to prevent loss

of NTG. Infusion of NTG was started at a rate of 1 μg kg^{-1} min^{-1}, which was increased until mean arterial pressure decreased to 50–65 mm Hg. The maximal infusion rate was chosen individually for each patient. NTG infusion was continued for no less than 1 h.

Arterial blood was obtained just before the start of infusion of NTG and 10 min after the maximal infusion rate was achieved. Blood was obtained in plastic tubes containing a 1:4 volume of acid citrate glucose solution (ACD) for measurement of platelet aggregation, intracellular calcium concentration and intracellular cGMP concentration. For measurement of concentrations of NTG and nitrite ions in plasma, 10-ml samples were anticoagulated with heparin 50 μl (50 u.). In order to investigate the effect of NTG on haemostasis, template bleeding times were measured in six patients before and 30 min after the start of infusion of NTG using Simplate (Organon teknica Co., Durham, NC, USA).

The control group consisting of seven patients (four men and three women, mean age 53.8 yr) also undergoing surgery of the hip joint, were anaesthetized using the same method but without infusion of NTG. Platelet aggregation, intracellular calcium concentration and template bleeding times were measured every hour during anaesthesia.

MEASUREMENT OF AGGREGATION AND INTRACELLULAR CALCIUM CONCENTRATION

Platelet rich plasma (PRP) was obtained as a supernatant after centrifugation of ACD-treated blood for 15 min at 800 rpm at room temperature. PRP was incubated with Fura-2 acetoxymethyl ester 3 mmol for 15 min at 37 °C and then centrifuged in the presence of apyrase 0.3 iu ml^{-1} at 1200 rpm for 15 min. Fura-2 loaded platelets were separated by discarding the supernatant and resuspended in Tyrode– Hepes buffer, pH 7.4.[11] Platelets were counted with a Coulter counter (Model T-540, Coulter Electronics Inc., Hialeah, Fla.) at a concentration of approximately 10^5 cells μl^{-1}. Contamination of the samples by leucocytes was less than 5% in all experiments. Intracellular calcium concentration ($[Ca^{2+}]_i$) and platelet aggregation were measured simultaneously with a calcium analyser (CAF-110, Jasco, Tokyo, Japan) with repeated alternating excitation wavelengths of 340 and 380 nm and measuring emission of 505 nm.[12] The platelet solution (490 μl) was adjusted so that the extracellular Ca^{2+} concentration was 1 mmol litre^{-1} by addition of $CaCl_2$ solution, and stirred for 5 min at 37 °C. After recording basal fluorescence intensity, platelets were stimulated with thrombin 0.01 iu ml^{-1}, and the change in fluorescence intensity was monitored for 6 min. Change in $[Ca^{2+}]_i$ was calculated as the relative ratio of fluorescence intensity at 340 nm to that at 380 nm ($R_{340/380}$).[13 14] Stimulation of thrombin-induced biphasic Ca^{2+} mobilization and the relative rates at the peak and at 6 min were recorded. $[Ca^{2+}]_i$ at each point was calculated according to the equation of Tsien, Rink and Poenie,[15] using K_d values of Fura-2 and Ca^{2+} of 224 nmol litre^{-1}. Data are expressed as increase in $[Ca^{2+}]_i$ from basal concentrations.

Aggregation measurements were performed according to the turbidimetric method of Born and Cross.[16] Inhibition of aggregation was measured as inhibition of light transmission at 6 min after addition of thrombin. All experiments were completed within 2 h of blood collection.

MEASUREMENT OF PLATELET CGMP CONCENTRATION

Concentrations of cGMP in platelets were measured by radioimmunoassay[17] using an RIA kit (Amersham International, Amersham, England). The washed platelet solution was added to the same volume of 20% trichloroacetic acid solution, then frozen immediately with dry ice and stored at −80 °C until the cGMP assay was done. Before performing the assay, cyclic nucleotides were extracted from the samples with ether and evaporated. The residues were dissolved in sodium acetate buffer 50 mmol litre^{-1} (pH 6.2) and acetylated with acetic anhydride and triethylamine (1:2) reagent. Data are expressed as pmol/10^9 platelets.

CONCENTRATION OF NITRITE ION AND NTG IN PLASMA

For measurement of nitrite ion concentration, plasma was deproteinized with 10% zinc sulphate solution and the supernatant was added to the same volume of Greiss reagent,[18] which forms a deep purple azo compound in the presence of nitrite ions. Absorbance intensity of the azo compound was measured at 540 nm using a 96-well microplate reader (Multiskan Biochromatic, Labsystems, Helsinki, Finland) with sodium nitrite solution as standard.

Plasma concentrations of NTG were measured using gas chromatography–negative ion chemical ionization–selected ion monitoring (GC–NICI–SIM) according to Idzu and colleagues,[19] with some modifications. The $[^3H_5, {}^{15}N_8]$ variant was used as an internal standard and 20 ng was added for each 2 ml of plasma. After deproteinization with Extrelut (#1003, Merck Co., Darmstadt, West Germany), NTG was extracted with n-hexane and purified on a Sephadex LH-20 column (Pharmacia Fine Chemicals, Uppsala, Sweden). A gas chromatography–mass spectrometry system (Japan Electron Optics Laboratory Ltd, Tokyo, Japan) was used with chloroform as the reagent gas.

MATERIALS

Apyrase (from potato) was obtained from Sigma Chemical Company, St Louis, MO, USA; Fura-2 AM from Dojindo Laboratories, Kumamoto, Japan; and nitroglycerin from Nihon Kayaku Co. Ltd, Tokyo, Japan. Thrombin was donated by Mochida Pharmaceutical Co. Ltd, Tokyo, Japan. All other compounds were purchased from commercial sources.

STATISTICAL ANALYSIS

Results are expressed as mean (SEM), with numbers of observations in parentheses. Statistical analyses were carried out using paired *t* tests, the level of significance being $P<0.05$. For analysis of the results of template bleeding time, the Wilcoxon signed rank test was used.

Results

Eight patients were given NTG solution i.v. at rates of 4–8 (mean 5.13 (SEM 0.52)) μg kg^{-1} min^{-1}. During infusion of NTG, mean systolic arterial pressure decreased from 77.5 (3.7) to 61.1 (2.7) mm Hg. Heart rate did not change after infusion of NTG (control, 87.0 (5.3) beat min^{-1}; during NTG infusion, 87.3 (7.6) beat min^{-1}).

PLATELET AGGREGATION AND $[Ca^{2+}]_i$

Platelet aggregation induced by thrombin 0.01 iu ml^{-1} was observed in all eight patients before infusion of NTG, and was inhibited in seven patients after infusion of NTG (table 1). Representative patterns of aggregation and change in the $R_{340/380}$ value (indicating a change in $[Ca^{2+}]_i$) are demonstrated in figure 1. The mean value of the change in $[Ca^{2+}]_i$ at the first peak induced by thrombin was 439.9 (68.7) nmol litre^{-1} in controls and 210.6 (38.7) nmol litre^{-1} after infusion of NTG ($P<0.05$). The mean value of the change in $[Ca^{2+}]_i$ at the second phase was 154.4 (19.8) nmol litre^{-1} in controls and 106.7 (18.0) nmol litre^{-1} after infusion of NTG ($P<0.05$). In contrast, seven patients who received nitrous oxide–isoflurane anaesthesia without infusion of NTG demonstrated no inhibition of platelet aggregation induced by the same dose of thrombin. The mean value of the change in $[Ca^{2+}]_i$ at the first peak was 491.9 (36.4) nmol litre^{-1} in controls and 460.3 (45.4) nmol litre^{-1} 1 h later. The mean value of the change in $[Ca^{2+}]_i$ at the second phase was 179.9 (22.8) nmol litre^{-1} in controls and 209.7 (44.6) nmol litre^{-1} 1 h after. These values were not significantly different.

Table 1 Platelet aggregation, changes in intraplatelet calcium concentrations and plasma concentrations of nitroglycerin. A representative profile (patient No. 4 in table 1) of the eight patients is shown. The ordinate at the right side represents the corresponding intraplatelet calcium concentration.

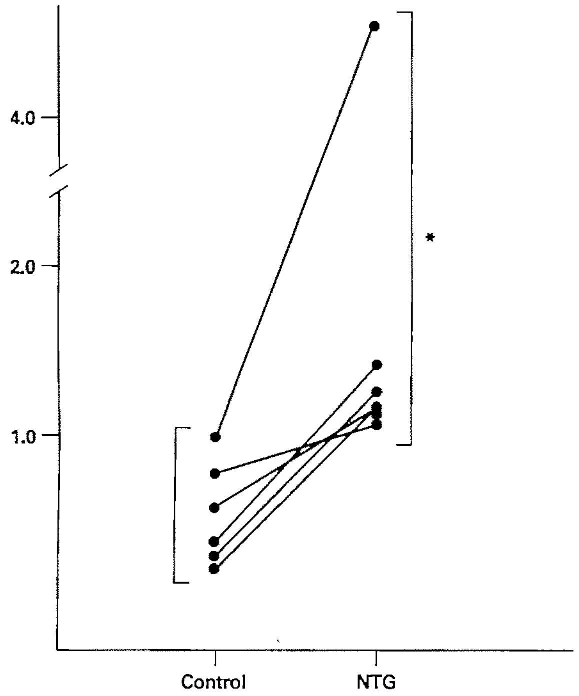

Figure 2 Changes in intraplatelet cGMP concentrations in controls and during nitroglycerin infusion (NTG) ($n=6$). Statistical comparisons by paired *t* test: $*P<0.05$.

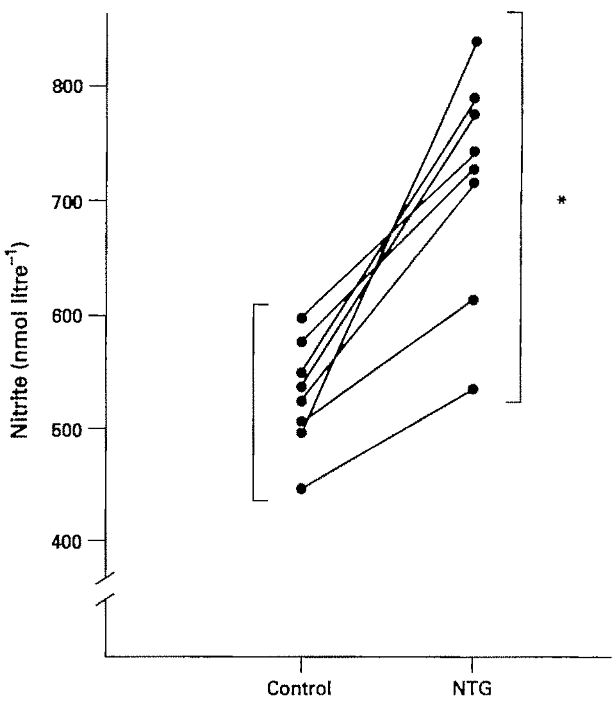

Figure 3 Changes in plasma nitrite ion in controls and during infusion of nitroglycerin (NTG) ($n=8$). Statistical comparisons by paired *t* test: $*P<0.05$.

CYCLIC GMP CONCENTRATION IN PLATELETS

The mean value of intracellular cGMP concentrations in platelets was 0.633 (0.098) pmol/10^9 platelets in the resting state, which increased significantly after infusion of NTG to 1.764 (0.578) pmol/10^9 platelets ($n=6$) (fig. 2). The increase in ratio ranged from 1.3- to 4.8-fold. Data were not obtained from two of eight patients.

PLASMA CONCENTRATIONS OF NTG AND NITRITE ION

During infusion, NTG concentrations in plasma ranged from 15 to 67 ng ml^{-1} (mean 38.3 (7.5) ng ml^{-1}) ($n=6$) corresponding to a concentration of the order of 10^{-8} mol litre^{-1}. Data were not obtained from two of eight patients.

Nitrite ion concentrations in plasma were measured before and during infusion of NTG. The mean concentration of nitrite ion before infusion was 532.6 (17.6) nmol litre^{-1} ($n=8$); after infusion, the mean value increased significantly to 724.4 (34.8) nmol litre^{-1} ($n=8$) (fig. 3). There was a correlation ($r^2=0.77$) between the increase in intraplatelet cGMP concentration and the increase in the concentration of nitrite ion.

TEMPLATE BLEEDING TIME

In six patients given NTG, template bleeding time was 8.38 (0.72) min before infusion of NTG and 8.25 (0.48) min during infusion (ns). In seven patients who received nitrous oxide–isoflurane anaesthesia, template bleeding time was 8.38 (0.72) min initially and 8.25 (0.48) min 30 min later (ns).

Discussion

In this study, we infused a large dose of NTG to induce hypotension, which resulted in increased intraplatelet cGMP concentrations and inhibition of increases in $[Ca^{2+}]_i$ and platelet aggregation. These changes may have been induced by increased concentrations of nitrite ion.

During activation, platelets show an increase in $[Ca^{2+}]_i$ and aggregation,[20] a process which may be modulated by intracellular cyclic 3', 5'-adenine monophosphate (cAMP) and cGMP.[21]

The inhibitory effect of NTG on the increase in $[Ca^{2+}]_i$ and platelet aggregation had been demonstrated in an earlier *in vitro* study.[22] Cyclic GMP was regarded as a mediator of the action: the increase in its intracellular concentration initiated the inhibitory process in platelets.[7] In contrast, in *in vivo* studies, infusion of NTG was reported to inhibit platelet aggregation,[23 24] although the precise mechanism by which platelet inhibition occurred was not investigated.

The effects of NTG on intraplatelet cGMP concentration, intracellular Ca^{2+} mobilization and aggregation were reported at NTG concentrations of approximately 10^{-4} mol litre^{-1} in *in vitro* studies.[6 22 25] Although we infused NTG at doses large enough to demonstrate clear decreases in arterial pressure, plasma concentrations of NTG only reached approximately 10^{-8} mol litre^{-1}. Kahlberg and colleagues' *in vivo* study[24] also showed that plasma concentrations of NTG were less than 10^{-8} mol litre^{-1}. Concentrations of NTG of the order of 10^{-8} mol litre^{-1} do not inhibit platelet function, according to the literature[7 10 22] and our previous *in vitro* pilot study (data not shown). The intracellular cGMP concentration and the increase in $[Ca^{2+}]_i$ were also reported not to be affected by the plasma concentration of NTG.[26] However, when platelets are incubated with reducible thiols, such as N-acetylcysteine, NTG-induced inhibition of platelet aggregation occurs at plasma NTG concentrations of the order of 10^{-8} mol litre^{-1}.[7] One *in vitro* study revealed that nitroso compounds reacted with thiols and formed S-nitrosothiols, which inhibited platelet aggregation.[27] Thereafter, liberation of nitric oxide from NTG was detected and this liberation was potentiated by added thiol.[28] S-nitrosothiols are regarded as active intermediates or carriers of nitric oxide.[29–31] Nitric oxide was also detected when NTG was incubated with vascular tissue[32,33] and it potentiated the increase in intraplatelet cGMP concentrations and inhibition of platelet aggregation.[34,35] The increase in the concentration of nitrite ion, the breakdown product of nitric oxide,[35] was also confirmed in our study. Accordingly, we proposed that nitric oxide was liberated as a consequence of bioconversion of NTG. This results in an increase in intraplatelet cGMP concentration and, simultaneously, inhibition of intracellular Ca^{2+} mobilization and platelet aggregation *in vivo*.

All data in this study were acquired during general anaesthesia with inhaled isoflurane in nitrous oxide. Therefore, we investigated the effects of these anaesthetics in seven patients and revealed that these anaesthetic procedures did not influence platelet function. Accordingly, inhibition of platelet aggregation and changes in intracellular calcium concentration which we demonstrated in this study were caused by NTG, although template bleeding time was not changed.

In summary, we have demonstrated *in vivo* that infusion of NTG increased cGMP concentrations in platelets and inhibited Ca^{2+} mobilization and platelet aggregation. Bioconversion of NTG was confirmed by the detection of a significant increase in nitrite ion in plasma. Therefore, nitric oxide could participate in the mechanism of these inhibitory effects. As the half-life of nitric oxide is reported to be very short, of the order of seconds,[36] these inhibitory effects should resolve promptly after cessation of infusion of NTG.

Validity of acoustic quantification colour kinesis for detection of left ventricular regional wall motion abnormalities: a transoesophageal echocardiographic study†

T. HARTMANN, N. KOLEV, A. BLAICHER, C. SPISS AND M. ZIMPFER

Summary

Transoesophageal echocardiography is a sensitive monitor for intraoperative myocardial ischaemia. Colour kinesis is a new technology for echocardiographic assessment of regional wall motion based on acoustic quantification. We have examined the feasibility and accuracy of quantitative segmental analysis of colour kinesis images to provide objective evaluation of systolic regional wall motion during the perioperative period using transoesophageal echocardiography (TOE). Two-dimensional echocardiograms were obtained in the transgastric short-axis and long-axis views in 60 patients with coronary artery disease undergoing non-cardiac surgery. End-systolic colour overlays superimposed on the grey scale images were obtained with colour kinesis to colour encode left ventricular endocardial motion throughout systole. These colour-encoded images were divided into segments and compared with corresponding conventional two-dimensional images. Six hundred of a potential 720 left ventricular wall segments were of sufficient resolution for grading by experts; they diagnosed wall motion abnormalities in 61 of these segments by a conventional method. In comparing the conventional TOE method with colour kinesis, there were 60 true positives, 482 true negatives, 57 false positives and 1 false negative result. This yielded a sensitivity of 98%, specificity of 89%, positive predictive value of 51% and negative predictive value of 100%. Translational and rotational movement of the heart and papillary muscle interference were common problems accounting for false positive diagnoses. We conclude that colour kinesis provides a basis for objective and on-line evaluation of left ventricular regional wall motion which is a sensitive but non-specific method. It may be a useful aid for the less experienced because it can potentially direct the anaesthetist's attention towards specific segments. (*Br. J. Anaesth.* 1997; **79**: 482–487).

Key words
Monitoring, echocardiography. Monitoring, colour kinesis. Heart, ischaemia. Heart, ventricles. Heart, myocardial function.

Transoesophageal echocardiography (TOE) is a sensitive and specific monitor for intraoperative myocardial ischaemia in patients with coronary artery disease.[1–3] However, conventional assessment of wall motion, based on visual interpretation of endocardial excursion, is experience-dependent and subjective.[1] To facilitate more objective evaluation of left ventricular endocardial motion, colour kinesis, a new technique based on acoustic quantification, has been developed and incorporated into a commercial ultrasound system (Hewlett-Packard Sonos 2500 and Vingmed CFM 800). Recently, Lang and colleagues[4] reported that colour kinesis images provided accurate and quantitative diagnosis of regional wall motion abnormalities using a transthoracic approach. Therefore, we compared prospectively left ventricular segmental wall motion patterns assessed by experts with those of colour kinesis in patients at risk of myocardial ischaemia undergoing TOE during non-cardiac surgery.

Patients and methods

The study was approved by our Institutional Review Board and written informed consent was obtained from each patient. We studied 60 patients (39 males) with coronary artery disease (CAD), at risk of CAD or hypertensive heart disease, aged 42–79 yr (mean 53 yr) who were in sinus rhythm with a heart rate of 45–101 beat min^{-1} (mean 65 (SD 14) beat min^{-1}). All patients were ASA class II of the multifactorial index of cardiac risk in non-cardiac surgery with total predictive points of 6–12. The majority was undergoing peripheral vascular surgery. Criteria for entry into the study included the presence of one of the following: (a) defined CAD, as indicated by previous myocardial infarction, typical angina or atypical angina with an ischaemic ECG response to exercise, or scintigraphic evidence of a myocardial perfusion defect; (b) high risk of CAD, suggested by previous or current vascular surgery or the presence

†Presented in part at the Annual Meeting of the American Society of Anaesthesiology, October 1996, New Orleans, LA, USA.

of at least two of the following cardiac risk factors: age >65 yr, hypertension, current smoker, serum cholesterol >6.2 mmol litre^{-1} or diabetes mellitus. We defined a previous myocardial infarction using ECG Minnesota Code criteria. Typical angina was defined as a history of chest pain with at least three of the following four characteristics: substernal location, precipitation by exercise or stress, duration <15 min and resolution after rest or nitroglycerin treatment. Atypical angina required two of the characteristics in addition to an ischaemic ECG response to exercise. Patients were excluded if they had abnormal myocardial repolarization (e.g. left bundle branch block, digitalis effect, left ventricular hypertrophy) or non-ischaemic causes of abnormal wall motion (e.g. bundle branch block, ventricular pacing, prosthetic valve, myocarditis or infiltrative disorder of the left ventricle).[5] Patients were studied at the University Hospital of Vienna between June 1994 and May 1996.

Patients were premedicated with diazepam 0.15 mg kg^{-1} i.v., 1 h before surgery. Anaesthesia was induced with fentanyl 3 μg kg^{-1} and thiopentone 4 mg kg^{-1}. After orotracheal intubation facilitated by vecuronium 100 μg kg^{-1}, the lungs were ventilated with 60% nitrous oxide in oxygen. Anaesthesia was maintained with increments of fentanyl and vecuronium with isoflurane up to 1%. A 7.5-fibreoptic thermodilution catheter (American Edwards) was inserted via the subclavian vein and advanced to the distal pulmonary artery. Correct positioning for recording PCWP was confirmed by observing a clear change in the pressure waveform when the balloon was inflated, and by measuring oxygen saturation of blood at the tip of the catheter. Before induction of anaesthesia, PCWP was measured during normal respiration, and after induction it was measured while the patient's lungs were disconnected temporarily from the ventilator.

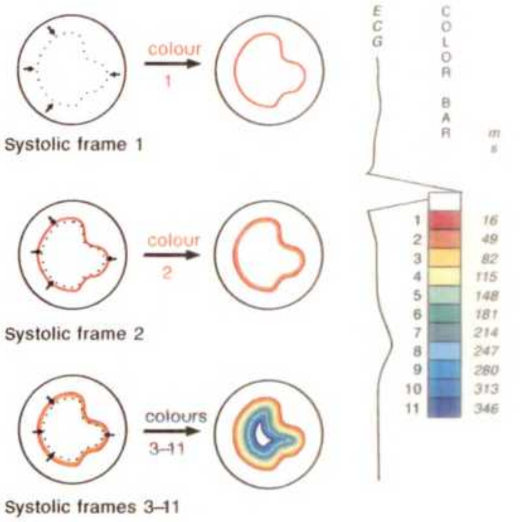

Figure 1 Principles of colour kinesis. The first frame is triggered with a delay from the R-wave to coincide with the start of left ventricular contraction and is assigned a colour which fills the space up to the border detected by the second frame. Successive frames are assigned different colours in sequence, as shown by the colour bar, and the spaces between successively detected borders are filled appropriately to give a composite multicolour rim that records the motion of different points on the circumference of the ventricular cavity during the time taken for the 11 frames.

COLOUR KINESIS: DESCRIPTION OF THE METHOD

Colour kinesis is an extension of the technology of acoustic quantification which uses changing values of tissue back-scatter between successive acoustic frames as a means of automatically tracing and displaying endocardial motion in real time. Acoustic quantification (Hewlett-Packard) has recently been validated against a variety of techniques by numerous investigators.[6 7] Colour kinesis processes the ultrasound back-scatter data and generates a binary mask image for each frame in which each pixel is classified as either blood or tissue. The pixel values at the transition from blood to tissue in this mask image are used to track systolic endocardial motion. The first frame in each cardiac cycle is triggered with a delay after the R-wave of the ECG so that it coincides with the start of inward movement of the left ventricular wall. The delay has a heart rate related default value but may need some visual–manual fine-tuning in some circumstances. Ten more frames follow the first successive intervals of 33 ms as the left ventricle contracts. The area between each new image of ventricular blood and the corresponding image in the preceding frame is filled with different shades of colour (fig. 1, left) superimposed on the grey scale image. A series of more or less concentric but irregular rims of colour accumulate from frame to frame in a way that reflects the time–motion history of endocardial excursion over the first 363 ms of the cardiac cycle (which usually covers most of the interval between isovolumic contraction and end-systole). The sequence of colours is indicated by the colour bar, with early systole being red–orange and late systole blue–purple (fig. 1, right): a default red in the image and in a signal box in the colour bar indicates outward segmental movement during systole (paradoxical motion). The width of any colour rim at any part of its circumference shows how much that portion of ventricular wall has moved inwards during the corresponding 33-ms inter-frame interval. The overlay of all 11 preceding colours on the last frame provides a multicoloured integrated display of the timing and magnitude of the inward motion of all endocardial segments during the 363 ms of the most recent systole. Thus the end-systolic width of the composite rim of colours represents the overall wall motion during most systoles. The display is updated beat by beat.

DATA ACQUISITION

Immediately after tracheal intubation, a multiplane probe with a 5-MHz phased-array transducer (Hewlett-Packard) was inserted into the oesophagus. The transducer was positioned and maintained at the level of the midpapillary muscles to obtain a short-axis view (T-scan) of the left ventricle and by steering the transducer to 90° to obtain a long-axis view (L-scan). The images were recorded on

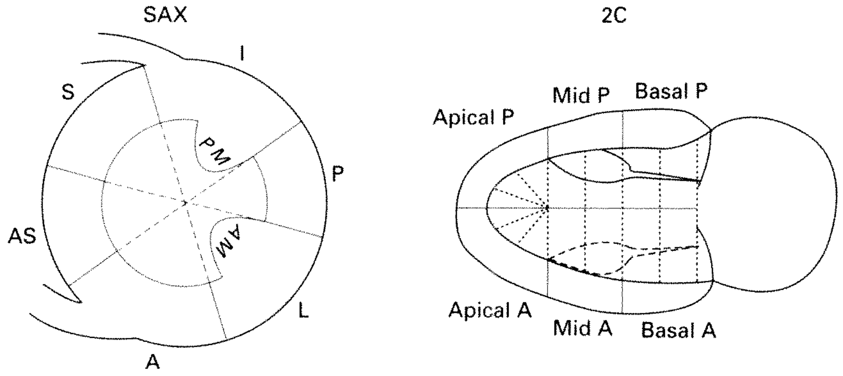

Figure 2 Segmentation schemes used for quantifying segmental analysis of endocardial wall motion according to the new recommendation of the American Society of Echocardiography. Short axis view (SAX) (transgastric): A=anterior; AS=anteroseptal; I=inferior; L=lateral; P=posterior; S=septal. (PM=posteromedial papillary muscle; AM=anterolateral papillary muscle). Longitudinal two-chamber view (2C) (transgastric): P=posterior; A=anterior.

videotape (Panasonic model AG-7350) for off-line analysis. After the image quality was optimized, the acoustic quantification system for endocardial border detection was activated. Gain controls (total and lateral gain, time-gain compensation) were adjusted to optimize tracing of the blood–endocardial interface within a preferred region of interest.[6] Colour kinesis was then activated for on-line encoding of endocardial excursion throughout systole. Image sequences containing colour kinesis data were obtained throughout the cardiac cycle and stored in a digital format for off-line analysis.

DATA ANALYSIS

Digital images were revived off-line using the continuous loop review mode of the echocardiographic system to ensure accurate tracking of the endocardial borers. In the transgastric short-axis view (T-scan), the segmentation originated from the left ventricular end-systolic cavity centroid. The zero degree line was defined by the centroid and a manually determined landmark represented by the junction between the right ventricular posterior wall endocardium and the interventricular septum.[9] The left ventricle was divided into six wedge-shaped sectors according to the new recommendations of the American Society of Echocardiography[10] (fig. 2, left). In the transgastric two-chamber views (L-scan), each image was divided initially into two sectors separated by a line (defined as the long-axis) connecting the distal apical endocardium with the end-systolic cavity centroid. Then, a series of perpendicular chords to the long axis of the ventricle, from the base to the midventricle, and a series of radii from the midpoint of the long axis of the ventricle to the apex, were constructed[8] (fig. 2, right). This scheme excluded mitral valve motion from the analysis.[9]

The type of colour kinesis throughout total ventricular systole was evaluated by reviewing the stored digital loops obtained in all patients. The fixed axis reference system was used for analysis.[8 11] The radial shortening of each segments as assessed by conventional two-dimensional images and colour overlay, was graded and scored (table 1).

All two-dimensional images were graded independently by two investigators using consensus, according to our laboratory published data[2]; these investigators were blinded to patient identity or colour kinesis. Colour kinesis detecting endocardial motion in each segment was measured off-line by a third blinded reader using callipers. To determine the effects of inter-examination variability, 200 scrambled samples from randomly chosen patients were re-read by the same observes, by consensus, approximately 2 months after the first reading.

STATISTICAL ANALYSIS

Data are given as mean (SD). Scores from colour-encoded acoustic quantification were compared with those derived by an experienced echocardiographer from two-dimensional images alone using correlation and simple regression analysis. Inter-observer

Table 1 Grading and scoring of the radial shortening of each segment, as assessed by conventional two-dimensional images and colour overlay

Class of motion	Conventional two-dimensional radial shortening	Colour kinesis		Scores
		No. of colours	Width of colour overlay	
Normal motion	>30%	11–9 colours	≥5 mm	1
Mild hypokinesis	10–30%	8–4 colours	<5 mm but >3 mm	2
Severe hypokinesis	>0 but <10%	3–1 colours	<3 mm	3
Akinesis	0	No colours		4
Dyskinesis	Systolic lengthening or bulging out	Red box on the colour bar		5

variability for each method was also evaluated. Difference were considered significant at $P<0.05$. The significance of differences in inter-observer interpretation of segmental systolic wall motion with two-dimensional echocardiography and the inter-technique (colour-encoded acoustic quantification) variability were compared for the proportions of pairs; 95% confidence intervals were estimated by $P \pm 1.96\, P\,(P-1)\, n$.

CALCULATIONS

Sensitivity=true positive/(true positive+false negative); specificity=true negative/(true negative+false positive); positive predictive value=true positive/all positives; and negative predictive value=true negative/all negatives.

Results

A total of 600 left ventricular wall segments were of sufficient resolution for grading by experts. Frame-by-frame analysis showed that the normal regional time of contraction ranged between 185 and 255 ms and was found to be consistent with inter-segment variations. Figure 3 gives an example of a normal contracting left ventricle from a transgastric short-axis view showing all 11 colours. In patients with hypokinesis there were reduced numbers of colours on the end-systolic overlay and thus reduced colour width/rim (fig. 4). In the majority of cases, endocardial shortening occurred early in systole. When no motion occurred, that is akinesis, the colour was absent. In figure 5, in the lateral segment of the left ventricular short-axis image, the colour rim shows outward systolic wall movement, for example paradoxical pixel transitions, and are all assigned the same red colour, regardless of the timing of transitions. It is evident that the colour bars are not quite the same in figures 3 and 4, compared with figure 5. In particular, in the lower part of the colour bar in figure 5 there is a red box which indicates that the "dyskinesis" feature is turned on, while in the images in figures 3 and 4 it is off. In fact, the statement that the colour bar reflects the timing of the endocardial motion is no longer the case for the paradoxical pixel transitions which are assigned

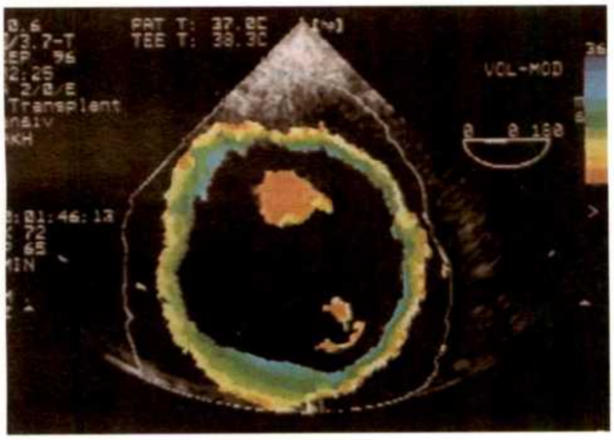

Figure 3 On-line assessment of regional wall motion using Hewlett-Packard colour kinesis technology. End-systolic colour-encoded image obtained in a normal subject in the transgastric short-axis view.

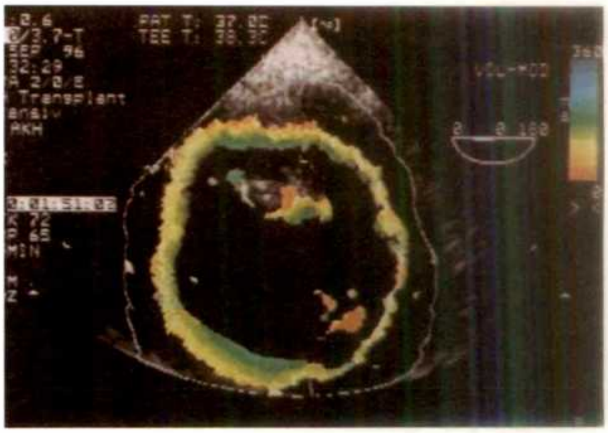

Figure 4 Example of colour kinesis data obtained from a patient with mild and severe hypokineis in the lateral and posterior segments of the left ventricular transgastric short-axis view.

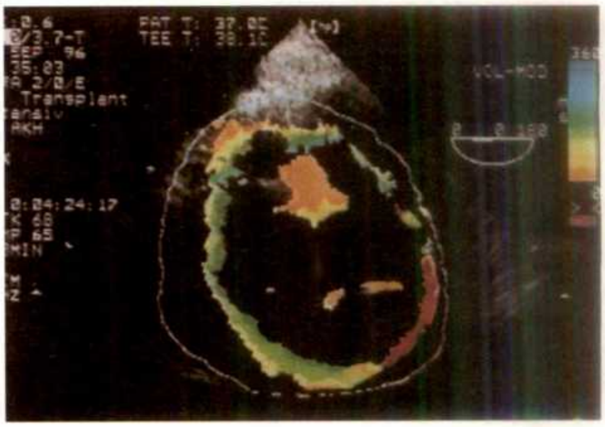

Figure 5 Example of colour kinesis data obtained from a patient with left ventricular dyskinesis showing outward systolic wall movement in the lateral segment (red) of the left ventricular transgastric short-axis scan. Note that there is a red box on the colour bar which indicates that the "dyskinesis" feature is turned on.

Table 2 Analysis of 600 left ventricular wall segments of which 61 showed conventional TOE-defined segmental wall motion abnormalities compared with whether the colour kinesis correctly diagnosed segmental wall motion abnormalities

	Conventional TOE		True positive	True negative	False positive	False negative	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)
	Ischaemia	No ischaemia								
Colour kinesis			60	482	57	1	98	89	51	100
Ischaemia	60	57								
No ischaemia	1	482								

the same red colour, regardless of the timing of transition.

Wall motion abnormalities were found in 61 of 600 segments by a conventional method. Comparing the conventional TOE method and colour kinesis, there were 60 true positives, 482 true negatives, 57 false positives and 1 false negative. This yielded a sensitivity of 98%, specificity of 89%, positive predictive value of 51% and negative predictive value of 100% (table 2). Inter-observer variability in the interpretation of regional systolic wall motion based on two-dimensional echocardiograms was 13.5%. The inter-technique variability between the conventional interpretation of two-dimensional echocardiograms and the above-described automated detection was found to be 26.2% ($P<0.05$).

Discussion

We have described our initial experience with a new technique, colour kinesis, designed to evaluate online ventricular regional wall motion patterns using TOE during operation. We chose to use a fixed reference system to analyse end-systolic conventional two-dimensional and colour kinesis images. This choice was made because colour kinesis adopts a fixed reference system for tracking endocardial motion by identical pixels in successive acoustic frames; in other words, a fixed frame of reference is used when colour kinesis images are created. Moreover, as each pixel in the colour overlay cannot be assigned more than one value, information regarding multiple pixel transition resulting from translation and rotation is not reflected in the end-systolic colour overlay. Although no consensus exists, floating reference systems have been recommended when attempting to quantify regional wall motion in the presence of translation.[11 12] These systems use superimposition of a systolic and diastolic centroid. When regional wall motion abnormalities are present, however, the systolic centroid is displaced towards the abnormality, thereby exaggerating the apparent wall motion in affected regions and diminishing the apparent wall motion in adjacent regions.[13 14] Because of this phenomenon, floating reference systems do not localize regional wall motion abnormalities as well as fixed reference systems in the absence of translation.[9]

This study demonstrated that colour kinesis correctly diagnosed 60 of 61 segmental wall motion abnormalities. Tracking of papillary muscles, instead of endocardium, accounted for one failure. However, colour kinesis falsely diagnosed 57 other segmental wall motion abnormalities. Translation and rotational movement of the heart, and prolongation of the pre-ejection period (in cases of ischaemia[8]) were common problems causing false positive diagnoses.

Recently, Lang and colleagues[4] used a transthoracic approach and colour kinesis (Hewlett-Packard), dividing colour-encoded images into segments using custom software. In each segment, pixels of different colours were counted and displayed as stacked histograms reflecting the magnitude and timing of regional endocardial excursion. The same authors found that histograms were highly consistent and reproducible in normal subjects. The patterns of contraction obtained in normal subjects were used as a reference for the objective automated interpretation of regional wall motion abnormalities, defined as deviations from this pattern. The inter-technique variability between the conventional interpretation of two-dimensional echocardiograms and the above-mentioned automated detection was found to be 17.0%. This inter-technique variability was not significantly different from the inter-observer variability of the conventional interpretation. They concluded that segmental analysis of colour kinesis images provided accurate quantitative diagnosis of regional wall motion abnormalities.

The time resolution of colour kinesis is limited to 33 ms by the present frame rate of 30 frames per second. This restricts the definition of endocardial motion at increased heart rates so that it is not accurate enough to provide sufficiently exact indices of regional motion of the left ventricular endocardium. On the other hand, the limited number of colours currently available for encoding may confound accurate acquisition in patients with heart rates less than 45 beat min^{-1} because the 363 ms duration of colour encoding may not be sufficient to cover enough of the systolic period. These limitations could be overcome by using faster frame rate imaging, together with an extended colour scale.

LABORATORY INVESTIGATIONS

Repeated enflurane anaesthetics and model predictions: a study of the variability in the predictive performance measures

P. M. VERMEULEN, J. G. C. LEROU, R. DIRKSEN, L. H. D. J. BOOIJ AND G. F. BORM

Summary

We quantified the total variability (reproducibility) and the within-patient but between repeat anaesthetics variability (repeatability) in measures which are used to judge the predictive performance of our physiological model. We studied 14 patients who received enflurane closed-circuit anaesthesia on two occasions. The end-tidal concentrations measured and those predicted served to calculate the predictive performance measures of the model: root mean squared error (rmse=total error), bias (systematic error) and scatter (error around the bias). The overall results were: rmse 15 (7) %, bias 0 (14) % and scatter 9 (3) % (grand mean (total SD)). The within-patient SD values were smaller for the rmse (4%) and bias (10%), but not for scatter (3%). The repeat rmse values and biases were linked to the first results. This implies that these performance measures depended partly on the patient. As there was no association between the personal performance measures and age, sex, body weight, body surface area or body mass index, these characteristics cannot be used to further tune the model. (*Br. J. Anaesth.* 1997; **79**: 488–496).

Key words
Anaesthetics volatile, enflurane. Equipment, breathing systems. Pharmacokinetics, models. Model, physiological.

Using average values of physiological variables and physicochemical data, we have defined a physiological model for closed-circuit inhalation anaesthesia.[1] It is capable of predicting end-expired concentrations after injection of a liquid anaesthetic into a closed-circuit breathing system. Previously we have evaluated the predictive performance of the model by examining the differences between the concentrations predicted and those measured in surgical patients. The observed prediction errors were condensed, per patient, into three single performance measures. These identify the total error size (rmse), systematic error (bias) and error around the bias (scatter). Close agreement between predictions and measurements was found in groups of patients anaesthetized with different volatile anaesthetics.[2–4]

Yet, if we wish to apply a model in a particular patient to predict the concentrations of a drug, variability in pharmacokinetic responses must be taken into account. Until now our clinical studies have provided information only on the between-patient variability, expressed in terms of variability in the predictive performance measures of the model, because different patients were studied only once. A major unresolved issue was the repeatability of the performance measures of the model in a patient presenting for repeated anaesthetic procedures.

Therefore, we studied patients who underwent enflurane closed-circuit anaesthesia twice. The objectives were: to evaluate the extent of correspondence between the predictive performance measures of the model obtained in the same patient on two occasions under similar clinical conditions; to determine if these measures varied more among than within patients; and to assess the association of the performance measures of the model with patient characteristics.

Patients and methods

Part of the methods has been described in detail previously and is summarized here together with the details necessary for this specific study.[1–4]

PATIENTS AND ANAESTHETIC MANAGEMENT

Earlier we completed a validation study of our system model for enflurane closed-circuit anaesthesia in 50 patients. They underwent elective eye surgical procedures, and 15 needed a second surgical intervention of the same type. After approval of the Institutional Ethics and Research Committee, these 15 consenting, Caucasian patients (ASA I or II) were enrolled in the study.

First anaesthetic procedure

Diazepam 5–10 mg and droperidol 2.5–5 mg were given orally 1 h before surgery. Anaesthesia was

induced with fentanyl 0.1–0.2 mg i.v. and a dose of thiopentone sufficient to abolish the eyelash reflex. Thereafter, vecuronium 0.1 mg kg^{-1} i.v. was administered. After placement of a cuffed tracheal tube, the lungs of the patients were ventilated artificially with a high fresh gas flow of oxygen and nitrous oxide in a 1:2 ratio until the end-tidal nitrogen concentration was less than 1 vol% or for a maximum of 5 min. Subsequently, the anaesthetic system was closed and closed-circuit anaesthesia commenced. The fresh gas flow of oxygen and nitrous oxide was adjusted manually to maintain the inspired oxygen concentration at 30–40 vol%. The end-tidal carbon dioxide concentration was 4.0–5.0 vol%.

Enflurane anaesthesia was administered using the liquid injection method by the same anaesthetist (P. M. V.). Boluses of liquid enflurane were injected into the expiratory limb of the system: one of 0.02 ml kg^{-1} (±0.1 ml) after the start of closed-circuit conditions and repeated increments of 0.01 ml kg^{-1} during maintenance. We did not use a rigid drug regimen, but modified enflurane administration to provide adequate anaesthesia as in good clinical practice. Therefore, we monitored carefully the patient's response to surgery by assessment of non-invasive arterial pressure measurement, heart rate and heart rate variability judged by ear with the aid of pulse oximetry, and also end-tidal enflurane concentration. Additional i.v. fentanyl 0.05–0.1 mg was given according to clinical needs.

Second anaesthetic procedure

This was separated from the first by at least 2 weeks. Patients received the same premedication. Anaesthesia was induced and maintained as described above. The same parameters for mechanical ventilation (frequency, tidal volume) were used. By design we did not aim to replicate the timetable of enflurane injections from the first anaesthetic. As in the first anaesthetic procedure, individual's anaesthetic needs under given surgical conditions prevailed as necessary.

For both procedures, we noted the times and volumes of liquid enflurane, and total volume administered (ml), and computed the average measured end-tidal enflurane concentration (vol%). To evaluate our anaesthetic management, we also expressed the average measured end-tidal enflurane and nitrous oxide concentrations as multiples of MAC corrected for age (mMAC) and calculated their sum (i.e. total mMAC).[5] Before evaluating the anaesthetic requirements and calculating the errors of prediction, we curtailed one of the two data files per patient, that is the one with the longest duration. Thus we considered only repeated observations for exactly the same duration.

INSTRUMENTATION

The anaesthetic equipment consisted of an Ohmeda Modulus CD anaesthesia system (Madison, WI, USA) with a standing bellows ventilator (Ohmeda 7850). The delivered tidal volume depends on the rate of fresh gas flow into the standing bellows ventilator.[6] Consequently, reducing and adjusting the fresh gas flow in order to provide closed-circuit conditions mostly necessitated frequent adjustments of tidal volume and the flowmeters at the beginning of closed-circuit anaesthesia. Five minutes were required until we were confident that tidal volume was equal during repeated measurements. Therefore, we only analysed data acquired after this initial non-steady state period.

A respiratory mass spectrometer (Centronic 200 MGA or QP9000; CaSE, Gillingham, England) continuously sampled gas at the Y-piece of the anaesthetic circuit via a side-stream sampling port (the sample flow is part of the model). The coefficient of variation of the mass spectrometer readings was 2%. Before starting each measurement we verified calibration of the mass spectrometer for enflurane with a calibration gas mixture containing 1% enflurane in 30% oxygen, 30% nitrous oxide and balance gas nitrogen (AGA Gas, Amsterdam, The Netherlands).

A personal computer system with a 12-bit analogue-to-digital board (Keithley Metrabyte, Taunton, MA, USA) processed the signals from the mass spectrometer. The data acquisition software was developed with the aid of ASYST (Keithley Metrabyte). On-line analysis of the respiratory waveforms allowed continuous monitoring in the operating room of the actual inspired and end-expired concentrations of nitrogen, oxygen, carbon dioxide, nitrous oxide, argon and enflurane. The trends of the inspired and end-expired concentrations of enflurane and oxygen of the last 20 min were also displayed continuously. The last end-expired enflurane concentration was saved for each 10-s period for further data processing.

THE MODEL AND ITS INPUT

The end-expired concentrations measured were compared with those predicted by our system model, version C, which does not assume a zero circulation time and accounts for non-pulmonary elimination of the anaesthetic agent.[3] Details of the model and its components are given in appendix 1. Data processing was a three-step process. During step one, the model input was generated by means of an ASYST application program. The model input consisted of

Table 1 Predictive performance measures: pe=prediction error (%), *n*=number of measurements per patient, pe_i is the *i*-th prediction error and me=mean prediction error. C_p and C_m=*p*redicted and *m*easured end-tidal concentrations of enflurane

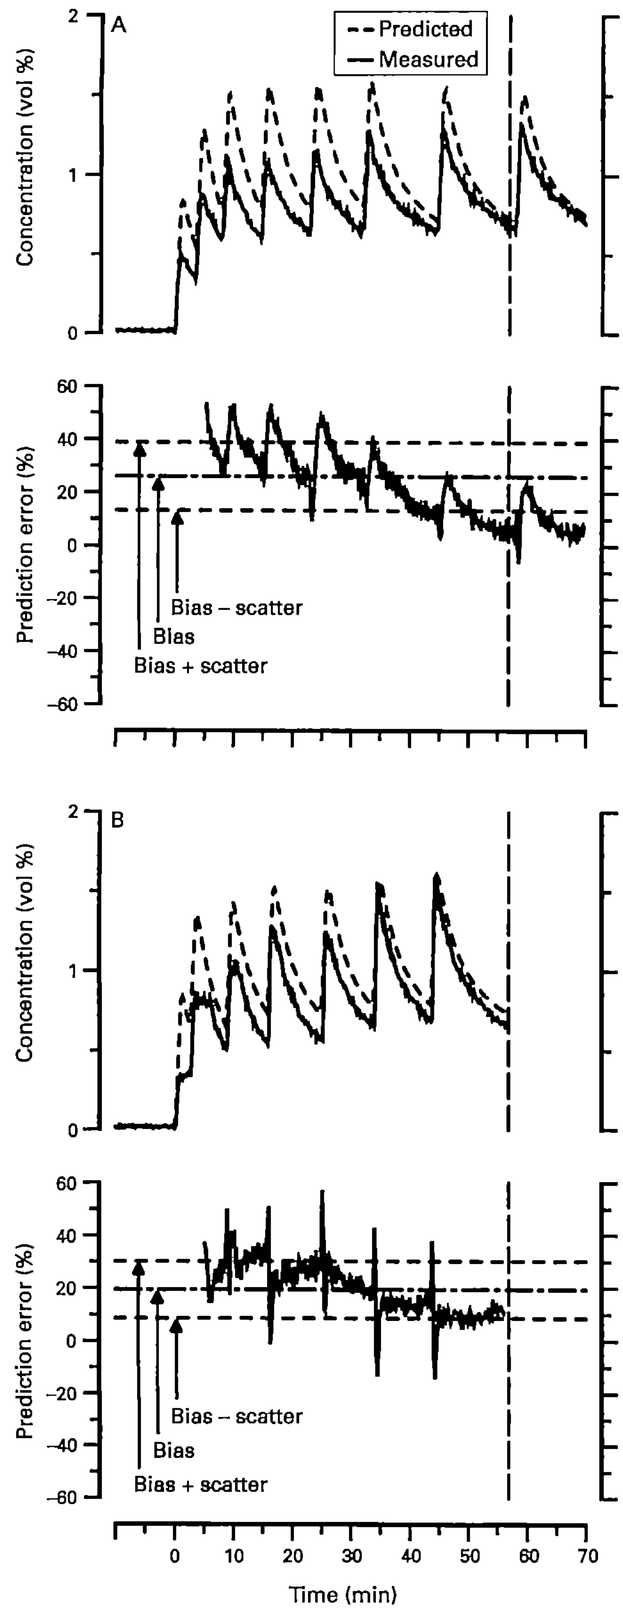

Figure 1 Repeated observations from a 22-yr-old female patient (weight 67 kg, height 1.75 m). A: Predicted and measured end-tidal enflurane concentrations, and prediction errors obtained during the first anaesthetic: one per 10-s period. The observed prediction errors were condensed into three predictive performance measures: total error size (rmse), systematic error (bias) and error around the bias (scatter). These were 29.0%, 26.1%, and 12.8%, respectively. B: The same variables as in (A) obtained during the repeated procedure. Rmse, bias and scatter were 22.2 %, 19.4 % and 10.8 %, respectively. The patient was anaesthetized with 7.0 ml of liquid enflurane administered in seven injections on both occasions. The vertical broken line shows how the data file with the longest duration was curtailed to match the durations of both anaesthetics.

patient data (age, sex, body weight and height) and the enflurane dosing schedule (timetable of injections with the amount of each enflurane increment). The amount of liquid enflurane per injection was converted into millilitres of vapour and supplied to the model as if the vapour were added to the anaesthetic system over a 60-s interval (i.e. the average time period necessary for the enflurane liquid to evaporate).

Throughout step two, our model generated the predicted time courses of the end-expired enflurane concentrations by running a TUTSIM simulation program (Meerman Automation, Neede, The Netherlands). In the final step three, by importing the predicted and measured data into another ASYST application program, the predictive performance measures of the model (see below) were calculated. For each patient and each anaesthetic procedure we predicted the end-expired concentrations by applying our system model.

PREDICTIVE PERFORMANCE MEASURES

Table 1 summarizes the measures which serve to determine the predictive performance of our model. The prediction error (pe) is the difference between a predicted and measured value of enflurane concentration, expressed as a percentage of the measured value: pe and squared prediction error (pe^2) are calculated for each time period of 10 s. These two quantities are used to provide the following three predictive performance measures.

(1) Root mean squared error (rmse). The mean squared error (mse) is the average of the squared prediction errors. Rmse is defined as $\sqrt{mse}$ and is a measure of the total error budget for an individual patient during one anaesthetic procedure. It is not influenced by the sign of the prediction errors and can be formulated as being composed of bias and scatter (table 1).

(2) Bias, that is the average of the prediction errors for an individual patient, is a measure of the systematic component of error. It can be either positive or negative, thus indicating over prediction or under prediction, respectively.

(3) Scatter is a measure of the variation of the prediction errors around their mean (bias) during one procedure.

These three measures were calculated for the first and the repeat anaesthetic procedure. Thus per patient we had a first and repeat rmse, bias and scatter, as illustrated in figure 1.

VARIABILITY MEASURES

The measures we used to describe the variability in the predictive performance measures were in accordance with the recently updated reports of the International Organization for Standardization ISO-5725, part 1 and 2, for repeated measurements.[7 8] Detailed information is given in appendix 2 and a summary follows. Three variances are calculated for each of the three performance measures (fig. 2).

Figure 2 Flow diagram for calculating the predictive performance measures of the model (columns A–E) and their variability measures (columns F–G) from p patients: A. patient number, B: number of anaesthetics; C: predicted (C_p) and measured (C_m) end-tidal enflurane concentrations. one per 10-s period; D: prediction error (pe) (%) and squared prediction error (pe^2): one per 10-s period; E: three predictive performance measures: rmse, bias and scatter, any one of these results given by y with the appropriate subscripts for patient and anaesthetic; F: mean ($\bar{y}$) and standard deviation (s) of each performance measure in a patient (mathematical expressions simplified for the particular case of two observations); G: grand mean of each of the predictive performance measures ($\bar{Y}$), with the within-patient (s^2_W), between-patient (s^2_B) and total (s^2_T) variance.

(s^2_W) is the average of individual variances. It is an indicator of the variation in a predictive performance measure within a patient (between repeat anaesthetics). The within-patient variability can yield an estimate of an expected performance measure for an individual from other values obtained in the same patient during former anaesthetics (=repeatability).

(2) Between-patient variance (s^2_B) is an indicator of the variation in the patient means around the grand mean.

(3) Total (or reproducibility) variance (s^2_T) combines the within- and between-patient variances: it reflects the overall variation in a predictive performance measure in the sample population. The total variability observed in all patients is the variability associated with estimating one of the performance measures for a random "unexplored" patient from the grand mean (=reproducibility). In the clinical environment this is the variability encountered most frequently.

Repeatability, between-patient and reproducibility SD (SD_W, SD_B, SD_T) were also calculated for each of the performance measures.

STATISTICAL METHODOLOGY

Graphical analysis of the data preceded formal statistical analysis. An analysis of variance was used for the predictive performance measures to calculate the components of variance according to Armitage and Berry.[9] Multiple regression analysis was used to study the association of age, sex, body weight, body mass index (BMI=weight height^{-2}) and body surface area (BSA, formula of DuBois and DuBois) with the average of the two repeated performance measures obtained per patient. The criterion for rejection of the null hypothesis was $P<0.05$ (two-sided).

Results

Initially, we studied 15 patients but data from one patient (original subject No. 10) were excluded from analysis. This patient had an extreme oculocardiac reflex during the second ophthalmic procedure requiring intervention. The clearly dissimilar clinical conditions (first *vs* repeat anaesthetic) yielded deviating results for rmse (8.44 *vs* 38.29%) and bias (3.14 *vs* 36.03%) although less for scatter (7.83 *vs* 12.95%), and precluded a meaningful analysis. Thus results of nine males and five females were analysed: mean age, body weight, BMI and BSA were 37.9 (range 14–66) yr, 71.8 (SD 10.4) kg, 22.6 (2.7) kg m^{-2} and 1.89 (0.15) m^2, respectively. Mean

Table 2 Details of the closed-circuit conditions and predictive performance measures (mean (SD)). n=14 for the first and repeat anaesthetic; n=28 for the grand mean results (third column). Total mMAC=sum of the average measured end-tidal enflurane and nitrous oxide concentrations, expressed as multiples of MAC corrected for age[5]

	First anaesthetic	Repeat anaesthetic	First and repeat anaesthetic
No. of injections	8.1 (2.1)	7.6 (1.4)	7.9 (1.8)
Injections per hour	8.7 (2.3)	8.1 (1.0)	8.4 (1.8)
Volume of liquid enflurane (ml)	7.2 (1.0)	7.0 (1.2)	7.1 (1.1)
Volume of liquid enflurane per hour (ml)	7.7 (0.9)	7.4 (1.0)	7.5 (1.0)
Average measured end-tidal enflurane (vol%)	0.98 (0.10)	0.93 (0.14)	0.95 (0.12)
Total mMAC	1.09 (0.13)	1.06 (0.12)	1.07 (0.12)
Rmse (%)	14.63 (7.43)	15.75 (6.76)	15.19 (7.09)
Bias (%)	−1.77 (13.23)	1.65 (15.08)	−0.06 (14.10)
Scatter (%)	9.47 (3.29)	8.53 (2.09)	9.00 (2.75)

duration of closed-circuit anaesthesia was 57.5 (12.9) min. Altogether these patients provided 9654 samples of intraoperative data and they were anaesthetized with a total of 198 ml of liquid enflurane for more than 27 h. Details on the repetitive closed-circuit conditions, recorded in table 2, corroborate that the closed-circuit conditions during both anaesthetics matched well. Only minor differences in the time schedules of the enflurane bolus injections were found. Table 2 also lists the predictive performance measures obtained from the first and repeat anaesthetic, and from the pooled data. The results from the latter data were: rmse 15 (7) %, bias 0 (14) % and scatter 9 (3) % (grand mean (SD$_T$)).

GRAPHICAL ANALYSIS

Simple scattergrams can be used to illustrate the association between the first and repeated observation on each of the performance measures.

(1) Figure 3A (left) demonstrates good agreement between repeated observations for total error size. Visual assessment of the extent of agreement between the two results is aided by the line of identity and a zone where the repeated observations differ by no more than ±5%. The maximum difference is approximately 11% (patient No. 12). Figure 3A (right) illustrates that the within-patient repeatability is not associated with the size of the

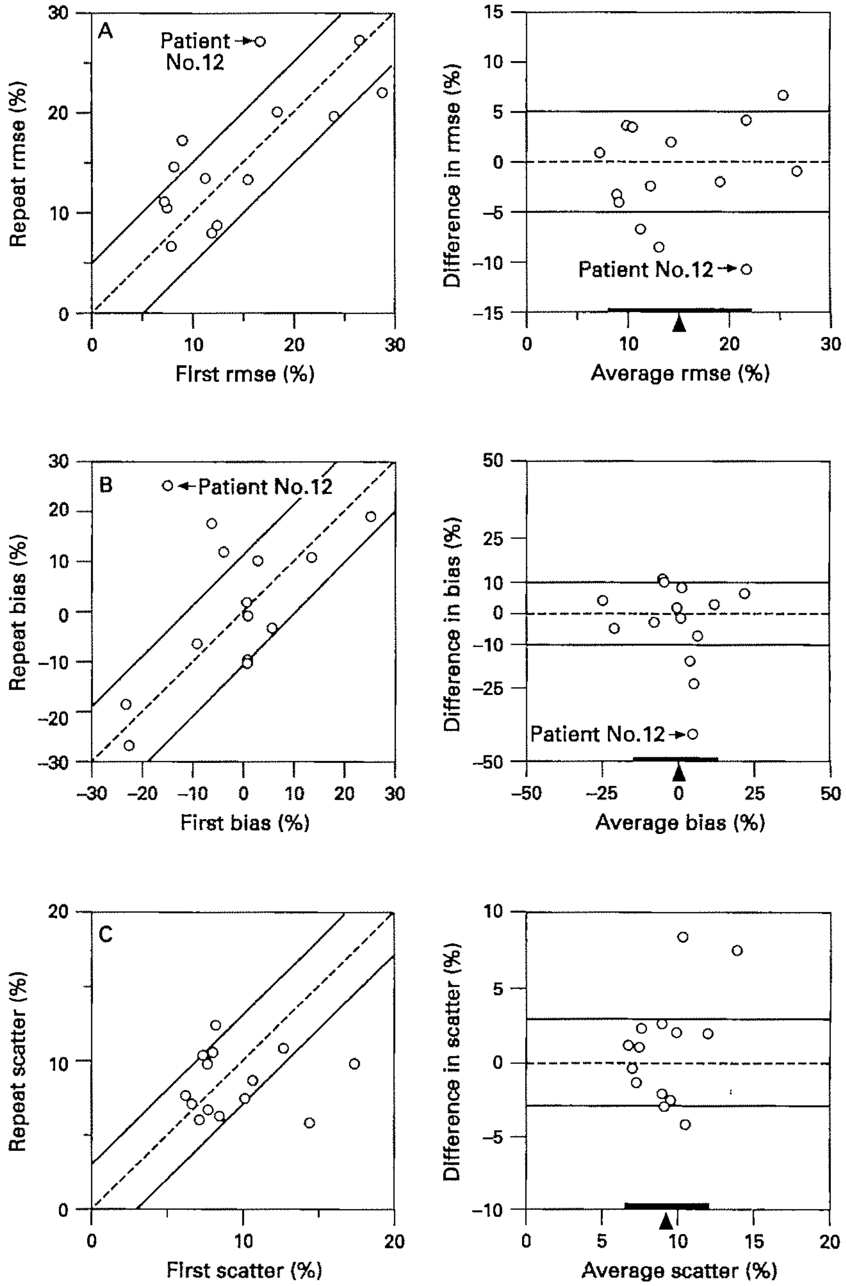

Figure 3 Left: scattergrams of the repeat *vs* first observations on each of the performance measures: A rmse (total error budget); B: bias (systematic component of performance error); and C: scatter (error around the bias). Broken lines=lines of identity, while full lines enclose a zone where the two observations differ by no more than ±5 % for rmse values, ±11% for biases and ±3% for scatters. Right: re-plotted data and lines from the scattergrams on the left, showing the differences between the repeated observations (first−repeat) *vs* the averages per patient for rmse values (A), biases (B) and scatters (C). ▲ and the thick lines on the abscissae represent the overall results: rmse 15 (7) %, bias 0 (14) % and scatter 9 (3) % (grand mean (SD$_T$)).

measurements as there is no relationship between the differences in repeated observations and averaged individual rmse values.

(2) Figure 3B (left) provides the two sets of systematic errors plotted against each other. The difference between the first and repeat bias is not greater than 11% for most patients (three patients are situated out of this zone). The greatest disparity in bias between repeated observations is −15 *vs* 25% (patient No. 12). Again, there is no relationship between the differences in repeated observations and averaged individual biases, as depicted in figure 3B (right).

(3) Figure 3C (left and right) indicates that scatters, although showing agreement to within ±3% for 11 patients, are heavily dispersed in a cloud without a clear link between the repeated observations.

From the right-hand graphs in figure 3 it is apparent that the spread of observations is less in the *Y*-direction than in the *X*-direction in figure 3A (right) and, apart from patient No. 12, also in figure 3B (right) but not in figure 3C (right).

ANALYSIS OF VARIANCE

Table 3 summarizes the key results of the variability in the three predictive performance measures. For rmse, the total variance s^2_T was nearly four-fold the within-patient variance s^2_W; thus s^2_W was much smaller than s^2_B. The ratio SD_T/SD_W was 1.98. For bias, s^2_T was twice as large as s^2_W , s^2_W was similar to s^2_B , and the ratio SD_T/SD_W was 1.39. For scatter, s^2_T was not much different from s^2_W , s^2_W was much larger than s^2_B, and the ratio SD_T/SD_W was 1.05.

Table 3 Variability in the predictive performance measures of the model obtained in 14 patients who received an enflurane anaesthetic twice. s^2_W=within-patient but between repeat anaesthetics (i.e. repeatability) variance, s^2_B=between-patient variance, s^2_T=total (i.e. reproducibility) variance, SD_W=repeatability standard deviation, SD_B=between-patient standard deviation, SD_T=reproducibility standard deviation[7 8]

	Rmse	Bias	Scatter
Minimum (%)	6.73	−26.66	5.89
Maximum (%)	29.07	26.12	17.46
s^2_W (%^{2})	12.80	102.64	6.85
s^2_B (%^{2})	37.45	97.68	0.74
s^2_T (%^{2})	50.24	200.32	7.59
SD_W (%)	3.58	10.13	2.62
SD_B (%)	6.12	9.88	0.86
SD_T (%)	7.09	14.10	2.75

MULTIPLE REGRESSION ANALYSIS

The average of the two repeated measurements obtained per individual, representing the best estimate of a "personal" result for each patient (e.g. a personal rmse or bias), was used to assess the potential influence of anthropometric patient characteristics on an individual's performance measures. Multiple regression analysis failed to detect a relationship between age, sex, body weight, BMI or BSA and the personal predictive performance measures.

Discussion

We have found that there was a link between the first and repeated measurement of the performance of the model. This was so for the measures rmse (total error size) and bias (systematic error), but not for scatter (fig. 3). This finding implies that most patients behaved similarly during both anaesthetics.

RATIONALE FOR A MODEL AND ITS VALIDATION

Our results are part of the necessary validation of a model. System models are used for clinical anaesthetic management, educational applications, research development, and to address economic or ecological issues. A physiological model is useful in a variety of "what happens if" scenarios, for example by predicting the effects of physiological perturbations on drug distribution.[10] Such a model is based on numerous simplifying assumptions, for example average values of physicochemical data and physiological variables are used. The disposition of a drug in any subject, however, is only predictable within limits as a result of variability in pharmacokinetics and pharmacodynamics.[11–15] It is critically important to know the impact of this variability on the imprecision and reliability of model-based predictions because far-reaching conclusions can be drawn from model behaviour. The variability we wished to study was reflected in the variation in the predictive performance measures of the model.

Our overall estimates of the performance measures of the model were in accordance with those found in a former validation study.[3] Standards to judge the validity of a system model for volatile anaesthetics have been defined previously.[4] We focused on the trueness, that is the closeness of agreement between predicted and measured concentrations.[7 16 17] A valid model should not under predict or over predict reality in a systematic way. Although it is reasonable to expect a degree of bias for each patient on each occasion, the group bias should approximate zero. This study yielded a group bias of 0 (14) % (grand mean (SD_T)). In addition, the total error size, assessed in terms of rmse, should be acceptable for most patients. Relying on biological variability in uptake found by several authors, we proposed that the total error size of a physiological model with zero group bias is acceptable if the rmse value of at least 68% of the subjects is <30 %.[4] In this study rmse was <30% for the 28 analysed observations.

EXTENT OF CORRESPONDENCE

It is most unlikely that repeated observations on the same patient would give identical values for each variable (rmse, bias or scatter) in every individual. Figure 3 illustrates the percentage of subjects showing agreement to within selected numbers of units. We used zones around the lines of identity of approximately one-sixth of the full axis range, thus indicating those patients whose repeated results differed little in comparison with the total range of variability between patients. In spite of a total range of 7–29%, the repeat rmse differed by no more than 5% from the first for 10 of 14 patients. The systematic error had a wide range (−27% to +26 %), whereas the difference between the first and repeat bias was not greater than 11% for most patients. If we translate the percentage bias into vol% of end-expired concentration, a difference of less than 11% implies that the systematic errors on the two occasions differed by less than 0.11 vol% for each vol% of anaesthetic. This is a small discrepancy in clinical terms. It appears that individuals who have or have not deviated from an anticipated pharmacological behaviour on one occasion tend to behave alike on an alternate similar occasion. Subjects can deviate, even grossly, from the grand mean, yet exhibit a high level of repeatability (observations in the top right and bottom left of figure 3B) (left). Therefore, model-based predictions have an extra clinical value.

COMPONENTS OF BIOLOGICAL VARIABILITY

We estimated that, although the repeat scatters differed little for most patients (fig. 3), 90% of the total variance resulted from within-patient variance (table 3). As scatter varies much more from one anaesthetic to the next in any one patient than it does between the average scatter for different patients (fig. 3C (right)), it may be that much of this scatter is not caused by variation within the patient but by some other cause.

We estimated for rmse and bias that 75% and 49%, respectively, of the total variance was caused by between-patient variance. In contrast with scatter, the variance in rmse was mainly attributable to systematic differences between patients. For bias, variance was distributed evenly among its two components.

Comparing the results of this study with those of others is difficult because data on recurrent measurements of inhaled anaesthetics are scarce and do not include estimates of both between-patient and within-patient but between repeat anaesthetic variabilities.[18–20] Studies in an other area of clinical research also found that prediction within patients was easier than that between patients when using a physiologically based formula, and that such information can be useful in clinical practice.[21]

ASSOCIATION WITH PATIENT CHARACTERISTICS

The high within-patient consistency was a reason for investigating the possible association of individual results for rmse or bias with age, sex, body weight, BMI or BSA. As in previous studies, a relationship between individual patient characteristics and performance measures could not be established.[2–4] This is not surprising because these data are primary inputs to the model. It uses an individualized input to calculate some physiological variables such as cardiac output and functional residual capacity. The characteristics studied cannot be used to improve the model. Additional, yet unknown, factors may contribute in a significant extent to an individual's pharmacokinetic response. Future research may reveal if our model-based predictions can be scaled further between individuals by other "personal" factors.

Our results ask the question whether we should save patient-related findings in a directly accessible "anaesthetic passport" (bearing the patient's anaesthetic finger printings). This may be an aid to anaesthetists in the future.[22] They may plan the anaesthetic of their patients on the basis of the average behaviour of a standard human, perhaps also according to institutional algorithms. Subsequently they may adapt the anaesthetic drug administration to tailor the anaesthetic to the physiological status of their patient. Models can facilitate these processes of decision making. But anaesthetists are also interested in identifying those patients who are likely to deviate from anticipated average behaviour. Our results suggest that determination of bias (or rmse) in a patient on one occasion, even if that bias is large, may be a useful predictor of bias on subsequent occasions. This is well illustrated in figure 3B (left), apart from patient No. 12. Other authors have shown that the correlation of anaesthetic uptake with easily observable patient characteristics is poor.[18 23] If the patient must receive another anaesthetic, the judicious use of data identified during a former anaesthetic may be the best basis available to adjust the "rules of thumb" which anaesthetists use when managing a patient.[24]

RESERVATIONS

The data showing high repeatability were gathered under similar clinical conditions. Therefore, repeatability values should not be extrapolated to apparently different conditions. Model-based drug regimens and algorithms are not intended as rigid recipes.[18] They offer a reasonable approach to anaesthetic management that must be individualized with the aid of clinical observations and vigilant monitoring of end-tidal concentrations and haemodynamic variables.[25]

A few patients with poor consistency and one outlier were found. Their presence suggests that the use of an adaptive model or feedback-controlled anaesthesia is worth considering for future development.[23 26 27] The control algorithms needed can be developed initially with the aid of a model which should be well validated and exhibit a realistic amount of variability such as that found in the present study.

We believe that repeatability data should be available to each research group studying the predictive performance of models, not only because it is important to separate within-patient from overall variability, but also because poor repeatability may highlight the need to re-examine the various procedures involved in gathering the data.[28]

In this era of multi-gas monitoring techniques and impending automated administration of volatile anaesthetics, there is still a definite role for well validated models of human physiology and pharmacology. The results for overall variability show that a dosing regimen based on our model is a useful starting strategy for administering closed-circuit inhalation anaesthesia; the results for within-patient variability suggest that a patient may benefit from using a starting regimen corrected from the findings obtained during a former anaesthetic.

Appendix 1

A concise non-mathematical account of the model is presented here. A comprehensive quantification and mathematical formulation have been presented elsewhere.[1] Our physiological model depicts the body and closed anaesthetic circuit as a system of 14 compartments (fig. 4). A liquid anaesthetic agent injected directly into the closed system is assumed to mix uniformly after vaporization with the contents of the closed breathing system. The anaesthetic agent is taken up from the alveolar space and distributed to the other tissue compartments: heart, brain, kidneys, liver (including all other well-perfused organs), muscles, connective tissue and adipose tissue. The model derives from the subject's age, sex, body weight and height, the other physiological variables, including deadspace, alveolar space, blood volume, cardiac output and tissue volumes.

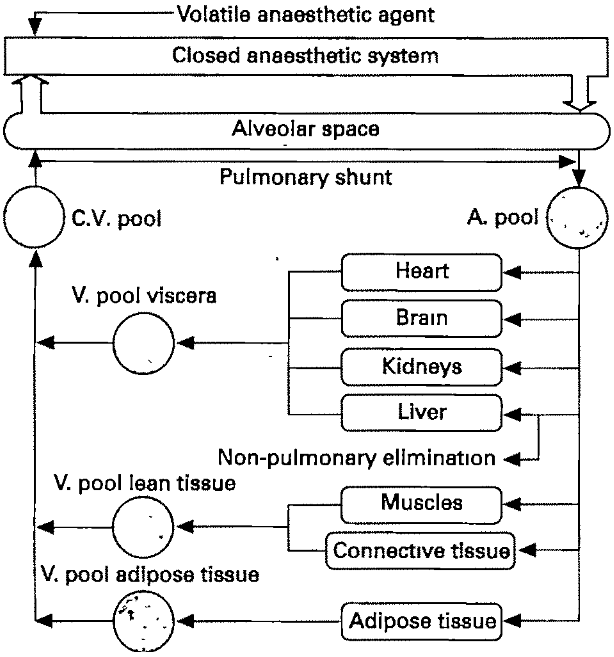

Figure 4 Simplified schematic diagram of the 14-compartment physiological model which includes the closed anaesthetic circuit and the patient tissues; the circles represent the blood pools (A.=arterial; (C.) V.=(central) venous).

Our system model differs from previous models for closed-circuit anaesthesia in four main ways. (1) Unlike the model of Lowe and Ernst it does not assume that the arterial concentration remains constant.[29] This implies that the model is able to predict breath-by-breath end-expired concentrations after bolus injections of a liquid anaesthetic agent into the closed system. (2) Our model does not assume that either the circulating times are zero or that venous blood is part of each tissue compartment. Rather we followed Mapleson's suggestions by introducing his concept of blood pools that mimics circulation times in the body.[30] (3) The model incorporates a non-pulmonary route of elimination for enflurane and halothane.[3 4] (4) Age-related blood-gas and tissue–blood partition coefficients can be introduced. For halothane we showed that this improved the accuracy of the model.[4]

Appendix 2

Suppose we have p patients called i ($i=1, 2, \ldots, p$) with m repeated observations on the same patient, giving a total of pm results for each of the three performance measures. If any one of these results is y_{ik} ($k=1, 2, \ldots, m$), then the individual mean result for patient i is:

$$\bar{y}_i=\frac{1}{m}\sum_{k=1}^{m} y_{ik}$$

The individual SD, that is a measure of the dispersion of the m repeated observations on the same subject, is given as:

$$s_i=\sqrt{\frac{1}{m-1}\sum_{k=1}^{m}(y_{ik}-\bar{y}_i)^2}$$

The grand mean for the sample population is:

$$\bar{Y}=\frac{1}{\mathrm{p}}\sum_{i=1}^{\mathrm{p}}\bar{y}_i$$

Three variances are calculated for each of the performance measures.

(1) Within-patient (or repeatability) variance s^2_{W} is the average of individual variances:

$$s^2_{\mathrm{W}}=\frac{1}{\mathrm{p}}\sum_{i=1}^{\mathrm{p}} s^2_i$$

(2) Between-patient variance s^2_{B} is an indicator of the variation in expected means between patients; this estimate is based on the distribution of patient means:

$$s^2_{\mathrm{B}}=\frac{1}{\mathrm{p}-1}\sum_{i=1}^{\mathrm{p}}(\bar{y}_i-\bar{Y})^2-\frac{s^2_{\mathrm{W}}}{m}$$

(3) Total sample population (or reproducibility) variance s^2_{T} combines within- and between-patient variances:

$$s^2_{\mathrm{T}}=s^2_{\mathrm{W}}+s^2_{\mathrm{B}}$$

The repeatability and reproducibility SD values are given by $\mathrm{SD_W}=\sqrt{s^2_{\mathrm{W}}}$ and $\mathrm{SD_T}=\sqrt{s^2_{\mathrm{T}}}$, respectively.

A physiological model of induction of anaesthesia with propofol in sheep. 1. Structure and estimation of variables

R. N. UPTON AND G. L. LUDBROOK

Summary

We describe a six-compartment physiological model of the kinetics and dynamics of induction of anaesthesia with propofol in sheep. It includes a faithful description of initial bolus kinetics caused by accurate representations of the inter-relationships between initial vascular mixing, lung kinetics and cardiac output, the use of the brain as the target organ for propofol anaesthesia (two-compartment sub-model with slight membrane limitation), a description of the effects of propofol-induced changes in cerebral blood flow and a combined description of systemic kinetics as two tissue pools. Variables for the model were estimated from an extensive *in vivo* data set using hybrid modelling. Propofol was characterized by rapid transit through the lungs, but a slower transit time though the brain, leading to significant delay between arterial blood concentrations and cerebral effects. (*Br. J. Anaesth.* 1997; **79**: 497–504).

Key words

Anaesthetics i.v., propofol. Anaesthetic techniques, induction. Induction, anaesthesia. Pharmacokinetics, propofol. Pharmacodynamics. Model, physiological. Sheep.

The pharmacokinetics and pharmacodynamics of propofol have been studied widely as a tool for increasing insight into its clinical use. The majority of studies have focused on measurements of the time course of the concentration of propofol in blood, and various measures of cerebral pharmacodynamic effects, including changes in the EEG and clinical indicators of depth of anaesthesia.[1–4] The resulting models of this process have been based typically on a two-, or more commonly, three-compartment systemic model with or without an effect compartment.[5 6]

While this approach can provide useful information, particularly with respect to targeting blood concentrations[6 7] for longer term administration by infusion, the limitations of this compartmental approach for bolus kinetics (or for rapid changes in infusion rate) have been well documented in the pharmacokinetic literature.[8–12] With respect to induction agents, these models fail to describe vascular mixing,[13 14] lung kinetics[8 15] and cerebral drug kinetics[16] in the vital period immediately after bolus injection.[17] Furthermore, these models are not suitable for describing the influence of the common physiological and pathophysiological conditions encountered in surgical patients.

These problems can be attributed to the lack of a physiological basis for these conventional compartmental models. Indeed, it has been shown that adding physiological descriptions of vascular mixing and lung kinetics improves their ability to describe initial bolus kinetics.[18 19] In our laboratory we have recently proposed a model of the first-pass passage of lignocaine from its venous injection site to one of its target organs for toxic effects—the heart.[20] This model embraced the importance of vascular mixing and lung kinetics, but also proposed a physiological site for drug action. Importantly, every aspect of this model was validated extensively using hybrid modelling techniques against an *in vivo* data set rather than arterial blood concentrations alone.

In this article, we extend this model to produce a physiologically realistic model of the kinetics and dynamics of induction of anaesthesia with propofol. The model is validated by comparison with recent experimental work from our laboratory using a chronically instrumented sheep preparation with which we have measured arterial and sagittal sinus (effluent blood from the brain) drug concentrations[21] simultaneously with measurements of cerebral blood flow[22] and an index of anaesthetic effects.[23 24] The essential structure of the model is sufficiently general in its form that it can be used to provide qualitative insights into induction of anaesthesia with propofol. Consequently, in this article the model is described and validated. In an accompanying article, the properties of the model and determinants of the induction process are examined in detail.

Methods and results

STRUCTURE OF THE MODEL

An overview of the structure of the model is presented first. It is similar to that proposed

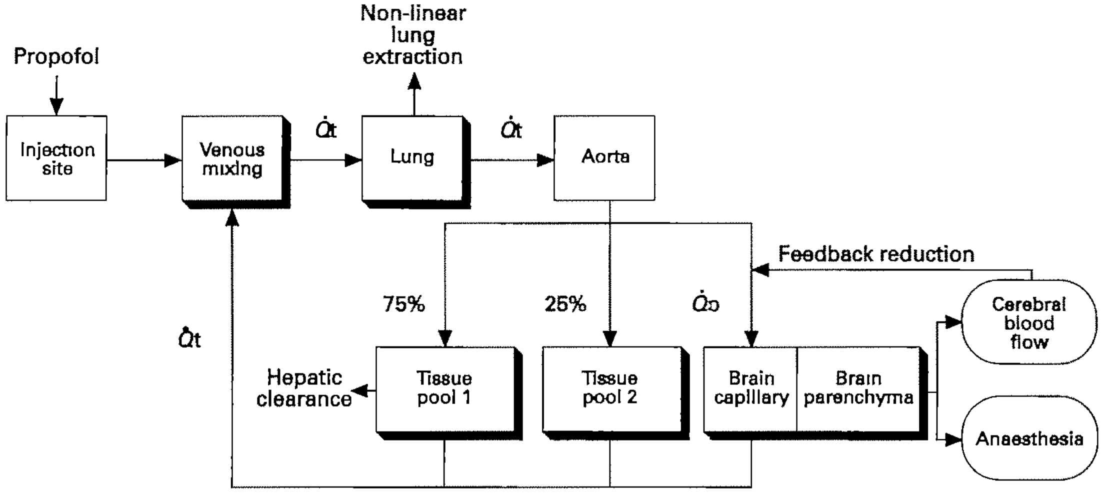

Figure 1 An overview of the model. The model is composed of six compartments (indicated as boxes with shadows) arranged in series and parallel in a circuit through which cardiac output ($\dot{Q}t$) flows. The effects of propofol on cerebral blood flow ($\dot{Q}b$) and depth of anaesthesia are related linearly to its concentration in the parenchymal compartment of the brain, but with a maximum reduction in cerebral blood flow of 50% of baseline. Propofol is removed by non-linear lung extraction and hepatic clearance.

previously,[20] with the addition of recirculation. The justification of this structure will be apparent when the variables of the model are validated subsequently against the *in vivo* experimental data.

The model is composed of six compartments in series and parallel (fig. 1). Consider the case where propofol is injected at a constant rate over a period T (e.g. 20 s) into the peripheral venous circulation to produce a square wave concentration peak of duration T. This "slug" of propofol (after Crawford[25]) travels in venous blood towards the lungs. The shape of this slug in the pulmonary artery is independent of the location of the injection site, and is determined in two steps in the model. First, the height of the square wave is adjusted for dilution with the remainder of cardiac output, with the new height given by the dose rate over cardiac output. This accounts for the basic indicator dilution aspect of the injection.[14 26] Second, dispersion of the peak because of intravascular mixing in transit from the injection site to the pulmonary artery is accounted for empirically by the passage of this peak through a small hypothetical well-stirred venous mixing compartment.

The peak then passes through the lungs where it is subject to distribution (described by a well-stirred compartment through which cardiac output flows) and a non-linear extraction term caused by metabolism. Emerging from the lungs in arterial blood, the peak is distributed to the remaining organs of the body. The brain was of special interest as the target organ for anaesthesia with propofol[21]—the kinetics were represented by a two-compartment model. The first compartment (nominally including capillary blood) was flow-limited, with slight membrane limitation in transfer to the second compartment (nominally including the parenchyma). The resultant sub-model of the brain has characteristics of both flow and membrane limitation,[27] and was modified further by a feedback loop accounting for propofol-induced reductions in cerebral blood flow. The maximum reduction in cerebral blood flow was set at 50% of baseline. The cerebral dynamic effects of propofol—its anaesthetic effects and ability to reduce cerebral metabolic rate and therefore cerebral blood flow—were related linearly to the concentration of propofol in the second compartment of the brain.

The kinetics of propofol in the remainder of the body were of interest to account for the effects of recirculation only, and the remainder of the body was therefore grouped together as compartments representing two tissue pools. The first was nominally the well-perfused organs, such as the liver and kidneys, received 75% of cardiac output (less cerebral blood flow) and included a first-order elimination process that represented hepatic clearance. The second received the remainder of the cardiac output and was nominally the poorly perfused tissues, such as muscle and fat. To complete the model, recirculated drug emerging from the brain and the tissue pools was returned to the venous circulation.

EQUATION SOLVING

The model was implemented as a set of differential equations (appendix 1) and was solved using the "Scientist" modelling package (Scientist for Windows, Version 2, Micromath, Salt Lake City, UT, USA), although any differential equation solver would be suitable. In general terms, the model could be used to predict the effect of propofol with respect to depth of anaesthesia and reductions in cerebral blood flow, and its concentrations in the brain parenchyma, pulmonary artery, aorta and sagittal sinus (venous effluent from the brain).

VARIABLE ESTIMATION

A shortcoming of many physiological models in the past has been the lack of a detailed *in vivo* experimental data set of simultaneously measured regional drug concentrations *and* blood flows with which to estimate the variables of the model. Our *in vivo* data set[21 24] allowed the use of hybrid physiological modelling[28 29] to estimate the variables of the model. The process used has been reported in detail previously,[20] but in general terms each component of the model (e.g. each compartment in fig. 1) is compared independently with the appropriate component of the data set. Input into each component is described by a series of empirical forcing functions that closely match the measured data, while the variables of the sub-model representing that component are determined by least squares fitting of the measured output data. For example, to model cerebral kinetics, arterial blood concentrations and cerebral blood flow (input to the brain) are fitted to empirical forcing functions. The variables of the chosen model of the brain (such as apparent volume of the brain) are then estimated by least squares curve-fitting by comparing the predicted and measured sagittal sinus concentrations (output of the brain). In this manner, the variables of large models can be estimated with a high degree of confidence independently of other aspects of the model. Detailed estimation of the variables is described below. The symbols and equations used are summarized in tables 1 and 2, and appendix 1.

Curve-fitting using a least squares algorithm was performed using the "Scientist" modelling package; the best fit was judged by maximization of the "model selection criteria (MSC)" of this package, which is the Akaike Information Criterion scaled to normalize for data sets of different magnitudes.[30] The higher the value of the MSC, the better the fit. The goodness of fit of individual data sets was also reported as an r^2 value.

Table 1 Variables of the model

Variable	Description
t	Time
C_{pa}	Pulmonary artery concentration
C_{art}	Arterial concentration
C_{ss}	Sagittal sinus concentration
C_{bp}	Brain parenchyma concentration
$\dot{Q}_{red}$	Percentage reduction in cerebral blood flow
A_{inc}	Percentage increase in "anaesthesia"

Venous mixing (lines 22–23 of appendix 1)

The fundamental indicator dilution basis of venous mixing is central to indicator methods for measuring cardiac output[26] and has been confirmed experimentally in the context of bolus injection.[14] However, dispersion of the peak in transit from the venous injection site to the pulmonary artery is a complex process.[31] An empirical but accurate method of accounting for dispersion with a small venous mixing compartment has been validated previously in our preparation.[20] The volume of the mixing compartment was shown to be 0.255 litre, and cardiac output itself has been measured repeatedly in our preparation—the baseline value was set at 5.6 litre min^{-1}.[32] This baseline value was used for simulation of "normal" data sets; in reality it should be acknowledged that there is sheep-to-sheep and day-to-day variation in cardiac output.[33]

Lung kinetics (lines 26–28 of appendix 1)

We have reported previously that the initial arterial concentrations of propofol after bolus injection were non-linear at low doses[21] and attributed this to non-linear extraction across the lung. The work of Mather and colleagues,[34] also using sheep, provided more information on this process. They showed that extraction occurred after prolonged infusions, and was therefore likely to be a result of metabolism (or essentially irreversible distribution). Re-analysis of their data showed that this metabolism was greatest at low concentrations and appeared to become saturated at higher concentrations (extraction of 68% at a steady state pulmonary artery concentration of 0.65 mg $litre^{-1}$, 26% at 3.4 mg $litre^{-1}$ and 15% at 8.35 mg $litre^{-1}$, respectively). It was found that the relationship between the inverse of extraction ($1/E_{lung}$) and the afferent pulmonary artery concentration (C_{pa}) could be described by the following equation (r^2=0.987; fig. 2):

$$\frac{1}{E_{lung}}=0.007C_{pa}+0.013 \qquad (1)$$

The remaining task was to estimate the

Table 2 Variables of the model for propofol in sheep

Variable	Description	Value used	Source
Dose	Total dose	200 mg	Default only
T	Duration of injection	20 s	Default only
$\dot{Q}t$	Cardiac output	5.6 litre min^{-1}	Measured / hybrid modelling
V_{mix}	Volume of the hypothetical venous mixing compartment	0.255 litre	Hybrid modelling
V_{lung}	Apparent volume of the lung	3.607 litre	Hybrid modelling
E_{lung}	Extraction by the lung	see equation (1)	Measured by Mather and colleagues[34]
V_{bc}	Apparent volume of brain capillary space	0.143±0.011 litre	Hybrid modelling
V_{bp}	Apparent volume of the brain parenchyma	0.035±0.009 litre	Hybrid modelling
PS	Membrane permeability of the brain	0.032±0.009 litre min^{-1}	Hybrid modelling
$\dot{Q}bb$	Baseline cerebral blood flow	0.04 litre min^{-1}	Measured
$\dot{Q}max$	Maximum reduction in cerebral blood flow	50%	Assumed
S_Q	Slope of linear pharmacodynamic model for cerebral blood flow	19.82±1.34	Hybrid modelling
S_A	Slope of linear pharmacodynamic model for anaesthesia	85±3	Hybrid modelling
V_1	Volume of tissue pool 1	15.67±2.95 litre	Hybrid modelling
V_2	Volume of tissue pool 2	570±131 litre	Hybrid modelling
F	Fraction of cardiac output going to V1	0.75	Assumed
Cl_{hep}	Hepatic clearance	1.12±0.25 litre min^{-1}	Measured by Mather and colleagues[34]

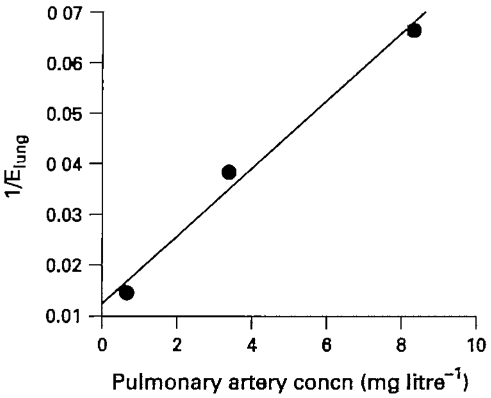

Figure 2 Steady state lung extraction (E_{lung}) of propofol against pulmonary artery concentration, re-analysed from the data of Mather and colleagues.[34] The r^2 value of the linear regression was 0.987.

distribution volume of the lung while taking into account this extraction (although it is relatively low at anaesthetic concentrations of propofol). Data for this purpose were the previously published initial increase in arterial concentrations of propofol measured during a 2-min infusion of propofol at a rate of 50 mg min^{-1}.[21] The time course of these arterial concentrations depends on two factors. First, in the absence of recirculation, concentrations increase to a steady-state value that depends only on the dose rate, cardiac output[14] and magnitude of the extraction process described by equation (1). The rate that they reach this value depends only on the magnitude of vascular mixing and the distribution of propofol in the lungs.

Hybrid modelling of the vascular mixing and lung kinetics subsystems, with dose as the input and arterial concentration as the output, was used to estimate the unknown variables of this sub-model—cardiac output (as it was not measured in this series of studies) and distribution kinetics in the lung. Measurement of cardiac output in this way is analogous to its measurement using indicator dilution principles.[26] Only data for the first 2 min of the infusion were used to ensure the measured concentrations were not distorted by recirculation, which is insignificant in this period.[20] In accord with our previous model, the lung distribution kinetics were represented initially as a single compartment through which cardiac output flowed.[20]

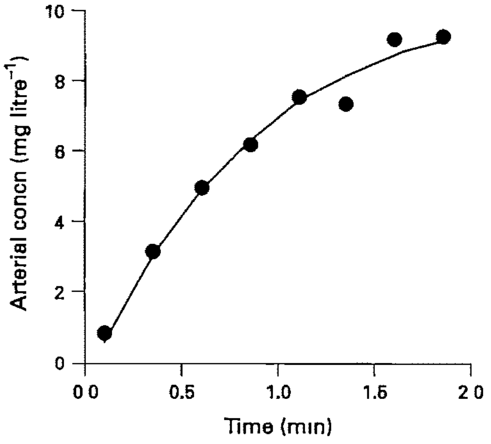

Figure 3 Measured (●) and fitted (line) arterial propofol concentrations used to estimate apparent volume of the lung.

It was found that this simple model allowed unique estimates of both cardiac output (mean 4.26 (SD 0.25) litre min^{-1} for these studies) and the apparent volume of the lung (mean 3.61 (SD 0.30) litre), and accurately described the measured data (r^2=0.997; MSC=3.62) (fig. 3). This equates to relatively rapid transit of propofol through the lung, with a mean transit time of 0.85 min. For comparison, the mean transit time of the vascular mixing process was 0.06 min.

Cerebral kinetics and dynamics (lines 31–38 of appendix 1)

The models of cerebral kinetics and dynamics were developed concurrently in order to account for the following observations, and were compared with the previously published studies of the cerebral kinetic and dynamics of propofol after a dose of 100 mg infused over 2 min.[21 24]

Relationships between propofol concentrations and cerebral blood flow. The pharmacokinetic modelling of anaesthetic agents is complicated as the majority of agents affect cerebral blood flow.[21 35] It was felt that the model should account for our previous observation that propofol reduced cerebral blood flow commensurate with reductions in cerebral metabolism.[24] The time course of these reductions was found to correlate linearly with the time course of mean brain concentrations of propofol (calculated using mass balance principles) but were delayed relative to the time course of arterial or effluent brain concentrations.[21] Baseline cerebral blood flow in the model was also set at 40 ml min^{-1} in accord with our previous observations.[22] The model should also be compatible with the observation that most anaesthetics can reduce cerebral blood flow only to a minimum of approximately 50% of baseline, consistent with abolishing synaptic function but not cellular respiration.[36]

Unpublished data from our laboratory have shown that propofol has minimal effect on cardiac output in sheep for bolus doses of up to 200 mg, in agreement with a report of a minor effect of propofol on cardiac output at "normal" blood concentrations in open chested pigs.[37] Therefore, the effects of propofol on cardiac output were not incorporated into the model.

Relationships between propofol concentrations and the depth of anaesthesia. To quantitate the time course of depth of anaesthesia after propofol administration in our preparation, we developed previously an algesimetry method based on the subcutaneous electrical current required to make a sheep withdraw its leg,[23] a concept similar to that used in the determination of minimum alveolar concentration (MAC) for volatile anaesthetic agents. While this method is restricted to measuring light planes of anaesthesia, it was found that this index correlated linearly with the time course of mean brain concentrations of propofol calculated using mass balance principles,[21] but again was delayed relative to arterial or sagittal sinus concentrations. The implication of these observations is that both this measure and other more traditional indicators of depth of anaesthesia, such as loss of consciousness and eyelash reflex, can be placed on the line of increasing brain concentrations thereby negating the temporal aspects of drug delivery to the brain.

The cerebral pharmacokinetic–pharmacodynamic model. Initial studies compared cerebral kinetics (as given by sagittal sinus concentrations and cerebral blood flow) with a single flow-limited compartment, and a membrane-limited two-compartment model, as used previously for thiopentone in this preparation.[16] Both were good descriptions of the data, with a slight statistical preference for the membrane-limited (r^2=0.995; MSC=4.91) over the flow-limited (r^2=0.992; MSC=4.55) model. However, the flow-limited compartment model was excluded further as this requires that mean brain concentrations and effluent sagittal sinus concentrations are proportional, and are delayed to equal extents relative to the cerebral effects. This is at odds with the two observations discussed in the previous section.

A property of the membrane-limited model is that sagittal sinus concentrations cannot be used to provide precise information on concentrations in the second compartment of the brain. This information was provided by allowing these concentrations to be related to the dynamic effects of propofol (both cerebral blood flow and depth of anaesthesia). Initially, more complex E_{max} and sigmoid E_{max} dynamic models[38] were examined, but it was found that the most appropriate model (i.e. highest value of r^2 and MSC together with precise estimates of variables) was one in which the concentration–effect relationships were linear with intercepts of zero, and the volume of the first compartment was set at the value determined for the kinetic data alone. An upper limit of 50% for reduction in cerebral blood flow was used, as discussed previously, on theoretical grounds only.

The resultant cerebral kinetic–dynamic model was a simple, yet elegant, description of the measured data, requiring estimation of only four variables (V_b, PS, S_Q, S_A) from three concurrent data sets (sagittal sinus concentrations, cerebral blood flow, depth of anaesthesia). Estimates of the variable values were precise (table 2). The kinetic component of the model was a good description of sagittal sinus concentrations (r^2=0.948; fig. 4), and the ratio of membrane permeability (PS) over flow of 0.8, places the model in the category of those that are both flow and membrane limited.[39] The dynamic components of the model were also good descriptions of the data (fig. 4) with r^2 values of 0.964 and 0.983 for blood flow and depth of anaesthesia, respectively. The overall MSC value for the combined kinetic–dynamic model was 3.77, and the respective r^2 values listed above show that approximately 95% of the variability in all three data sets could be accounted for by the model.

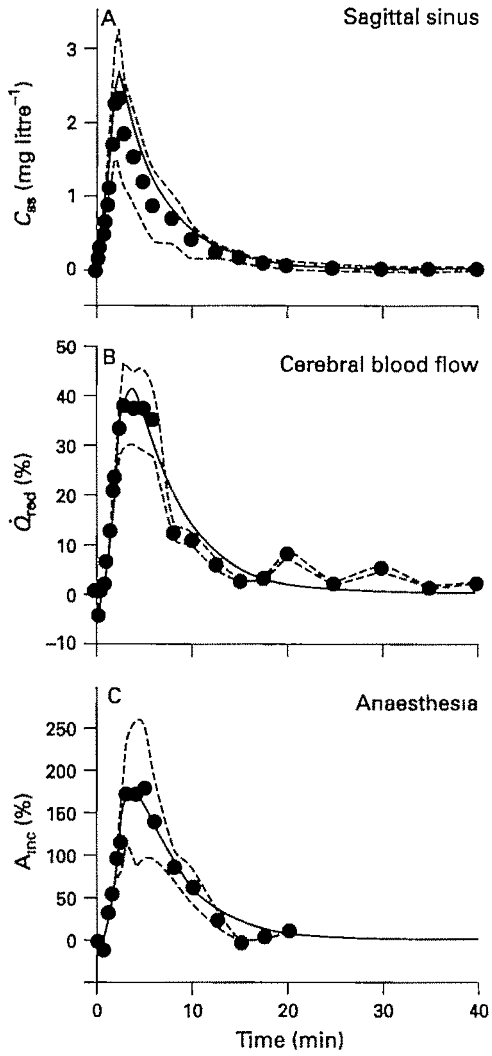

Figure 4 Measured data and best fit of the combined cerebral kinetic–dynamic model. A: Measured sagittal sinus concentrations (●) (broken lines=upper and lower 95% confidence limits) for propofol 100 mg infused over 2 min, together with the fitted concentrations (solid line). B: Equivalent data for measured cerebral blood flow expressed as percent reduction from baseline ($\dot{Q}_{red}$). Note that the model does not predict transient reductions in flow often measured after emergence from anaesthesia between 20 and 30 min.
C: Equivalent data for depth of anaesthesia (as given by the current required for leg withdrawal) expressed as a percentage increase from baseline (A_{inc}). Note that the experimental measurements were stopped at 20 min when baseline had been re-established.

Systemic kinetics (lines 45–46 of appendix 1)

The systemic kinetic variables of the model were estimated from pilot data from our sheep preparation describing arterial concentrations of propofol during and after a 45-min infusion of propofol at a rate of 10 mg min^{-1} (n=3 sheep). It was felt that two tissue pools were appropriate for systemic kinetics, the second pool accounting for the widely acknowledged "deep" distribution of propofol.[5] These pools received fixed fractions of 75% and 25%, respectively, of cardiac output (less cerebral blood flow). Initial studies showed that the model was under-determined if clearance, as a result of elimination and deep distribution kinetics, was estimated simultaneously, which is consistent with our previous work showing that these processes are indistinguishable, even at steady state, in some circumstances.[40] Fortunately, Mather and colleagues[34] made direct measurements of propofol

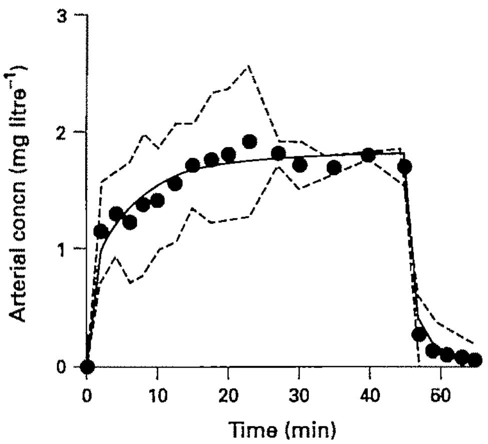

Figure 5 Measured arterial propofol concentrations (●) (broken lines=upper and lower 95% confidence limits) used to estimate systemic kinetic variables cardiac output and the volumes of tissue pools 1 and 2, and the best fit of the model (solid line).

organ clearance in sheep, and found that with the exception of pulmonary extraction accounted for above, clearance was predominantly hepatic and was relatively constant (1.13 (SD 0.25) litre min^{-1}) with almost complete extraction of propofol by the liver. Consequently, clearance from tissue pool 1 was set at this value. The unknowns to be determined from the 45-min infusion data were therefore cardiac output and the volume of tissue pools 1 and 2. These were estimated with an adequate degree of confidence from the data (6.41 (SD 0.1) litre min^{-1}, 15.7 (2.9) litre, 570 (131) litre, respectively), and were a good fit of the measured data ($r^2=0.995$; MSC=3.75) (fig. 5).

COMPARISON WITH INDEPENDENT DATA SET

The good fits of the data shown in figures 2–5 illustrate that the structure of the sub-models used were appropriate descriptions of the relevant data sets. To examine the overall integrity of the completed model, it was used *de novo* to predict a set of data that could be compared with an independent data set not used in the validation steps of the model. The data set chosen was pilot data ($n=3$) of sagittal sinus concentrations of propofol after a 45-min infusion at a rate of 10 mg min^{-1}. There was good agreement between simulated and measured concentrations (fig. 6), thereby showing that the model is capable of accurate *de novo* predictions.

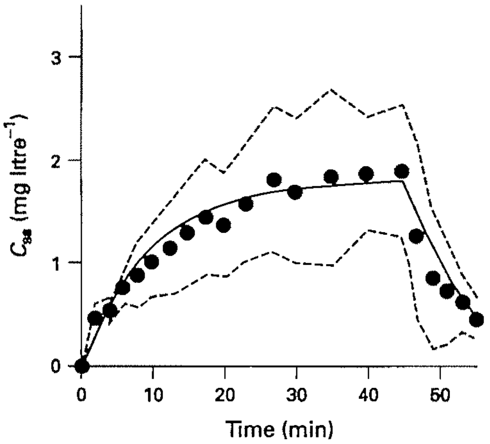

Figure 6 Estimated variables (table 2) were used with the model to simulate sagittal sinus concentrations resulting after an infusion of propofol 10 mg min^{-1} for 45 min. These were compared with an independent data set (i.e. data not used to validate the model) consisting of measured concentrations from a pilot study ($n=3$). There was good agreement between simulated (solid line) and measured (●) data (broken lines= upper and lower 95% confidence limits).

Discussion

For describing bolus kinetics, traditional compartmental pharmacokinetic models invariably feature a central compartment to which drug is added instantaneously or as a very short infusion. A common problem has been highly variable estimates of this central volume, which appears to relate to the time[9] and site[2] of the first blood sample, and the physiological state of the patient. Two important points arise from this article. First, together with the work of others,[18 19] it has shown that in physiological terms the central compartment is in fact a poor representation of the interactions between vascular mixing, lung kinetics and cardiac output, and that taking these factors into account can greatly improve the description of bolus kinetics. Second, the initial concentrations in the central compartment are poorly related to the important cerebral effects of propofol, and these are described better by using the brain as the target organ for these effects.

A drawback of the increased complexity of our model is the non-intuitive nature of the interactions between the various components, but this can be addressed by using a working version of the model to simulate various data sets.[41] Importantly, this increased complexity allows determinants of the onset of anaesthesia to be described by variables directly relevant to the practice of anaesthesia (e.g. cardiac output and cerebral blood flow), which are examined in more detail in an accompanying article.[41] A traditional problem of physiological models, that of estimating large numbers of variables from an under determined data set,[29] has been circumvented by hybrid modelling of *in vivo* data such that all variables were estimated confidently and essentially independently of each other.

The limitations of the present model are in addition to those discussed for the previous model of first-pass concentrations,[20] but in general amount to "fine tuning" of the model rather than structural flaws. These include the fact that it is based on animal data (discussed in more detail in our accompanying article[41]), does not account for lag during passage through blood vessels (insignificant when drug transit times through organs are high relative to vascular transit times), has a poor description of injection site concentrations (not of direct clinical relevance) and does not account for protein binding (can be ignored in individuals if binding is linear and protein concentrations are constant after injection) or tachyphylaxis (overall role uncertain). It should also be remembered that the model does not account for the haemodynamic effects of propofol, which may significantly influence its use, nor does it account for blood flow changes secondary to respiratory depression in unventilated animals.

The present model (and data upon which it is based) has several implications for other models of propofol kinetics. First, the model incorporates two sources of non-linearity: drug-induced cerebral blood flow changes and concentration-dependent lung extraction. Therefore, models that are entirely linear in their structure are likely to be in error when predicting the outcome of large changes in dose. Second, the model provides some insight into the nature of the commonly used effect compartment rate constant k_{e0}, relating blood concentration (usually arterial) to a measured effect.[42 43] In the case of propofol, our study revealed k_{e0} to be a composite of flow and permeability terms describing entry of propofol into brain tissue and, for the reasons described above, would not have the properties of linearity and first-order kinetics usually ascribed to k_{e0}. However, rough calculations show that the effect delay predicted by this model could be approximated by an effect half-life relative to arterial blood that ranged from 3.5 to 7 min. The slight membrane limitation in the model of the cerebral kinetics of propofol is supported by recent data in human.[44]

In summary, we propose that the model provides useful insight into which kinetic and dynamic processes contribute to the onset and offset of anaesthesia with propofol.

Appendix 1

EQUATIONS DESCRIBING THE MODEL

The equations of the model, written in a form suitable for the differential equation solver and modelling environment "Scientist" (Scientist for Windows, Version 2, Micromath, Salt Lake City, UT, USA). The conventions used are common to many programming languages, but note that an apostrophe after a variable indicates a differential with respect to time (thus C' is dC/dt) and that the "pulse" function is used to generate a square wave input. Annotations are preceded by "//", and symbols are explained in detail in tables 1 and 2. The line numbers on the right are for reference purposes only. In this example, 200 mg is administered over 30 s.

A physiological model of induction of anaesthesia with propofol in sheep. 2. Model analysis and implications for dose requirements

G. L. LUDBROOK AND R. N. UPTON

Summary

The determinants of induction of anaesthesia with propofol, and their implications for dose requirements, were analysed using a physiological model of the process, validated previously using sheep data. The maximum depth of anaesthesia occurred 2–3 min after cessation of injection. Injection over 2 min minimized the induction dose. More rapid injection (<1 min) did not significantly hasten induction, but increased dose requirements and produced large peak arterial concentrations, potentially risking increased hypotension. Cardiac output and cerebral blood flow were important determinants of the induction process. Increased cardiac output decreased the duration of anaesthesia, while increased cerebral blood flow increased the depth but not duration of anaesthesia. The influence on dose requirements of propofol of factors such as anxiety, hyperventilation, age and co-induction with other drugs may be interpreted in terms of their effect on cardiac output and cerebral blood flow. (*Br. J. Anaesth.* 1997; **79**: 505–513).

Key words
Anaesthetics i.v., propofol. Anaesthetic techniques, induction. Induction, anaesthesia. Pharmacokinetics, propofol. Pharmacodynamics Model, physiological. Sheep.

In an accompanying article,[1] we described and validated a physiological model of the kinetics and dynamics of induction of anaesthesia with propofol in sheep. In brief, the model included a small vascular mixing compartment, a lung compartment with non-linear extraction, the brain represented as a two-compartment model with slight membrane limitation (cerebral effects, including feedback reduction in cerebral blood flow were related linearly to propofol concentrations in the second compartment of the brain), and two compartments nominally representing moderately and poorly perfused tissues, respectively. First-order hepatic clearance was included in the moderately perfused tissue pool. Each component of the model was validated[1] against an extensive previously published *in vivo* data set collected in instrumented sheep,[2–4] such that the model was shown to be capable of accurate *de novo* predictions.[1]

In this companion article, we analyse the structure of the model in order to illustrate its fundamental properties and its implications for dose requirements of propofol in various circumstances. The properties of models of this complexity which represent convoluted physiological systems are not intuitively obvious, but become apparent by systematically examining the influence of each component or variables of the model.

Methods

The detailed structure of the model and estimation of its variables have been published previously.[1 5] The predictions of the model were examined by simulation of a variety of physiological states and dose regimens (elaborated below). The results of simulations were summarized by their influence on the time and magnitude of peak propofol concentrations in arterial blood and brain. The dynamic outcome was summarized by their effect on duration and depth of anaesthesia. We have shown previously that brain concentrations of propofol were related linearly to its major cerebral dynamic effects—reductions in cerebral blood flow and changes in depth of anaesthesia.[1 3] Therefore, it was assumed that there was a threshold brain concentration of propofol for the onset and offset of loss of consciousness. While the magnitude of this threshold depends on the magnitude of the pharmacodynamic response to propofol in the brain, the level of surgical stimulus and other factors, this analysis is valid for comparison purposes. A value of 2 mg litre^{-1} was chosen for the threshold, which was consistent with our previous observations.[3] Note that as the brain was modelled as an apparent distribution volume, 2 mg litre^{-1} is an apparent brain concentration which must be multiplied by the brain:blood partition coefficient to give the true brain concentration.[6] The time of onset of anaesthesia (loss of consciousness) was the time the apparent brain concentrations first reached 2 mg litre^{-1}, the time of maximum depth of anaesthesia was the time of peak brain concentrations (expressed as percentage of normal for comparison purposes), while duration of anaesthesia was the length of time the brain concentrations remained greater than 2 mg litre^{-1}.

R. N. UPTON, BSC, PHD, G. L. LUDBROOK, MB, BS, FANZCA, Department of Anaesthesia and Intensive Care, Royal Adelaide Hospital, University of Adelaide, North Terrace, Adelaide, SA 5005, Australia. Accepted for publication: May 26, 1997.
Correspondence to R. N. U.

The predictions of the model were examined for two dose regimens of propofol—a bolus injection of 200 mg over 20 s ("bolus") and an infusion of 40 mg min^{-1} for 5 min ("infusion"). These correspond in general terms to the two major clinical methods used for induction of anaesthesia with this agent.

STRUCTURAL ANALYSIS

The importance of various structural components of the model was analysed by systematically removing them from the model; these were drug-induced changes in cerebral blood flow, recirculation, hepatic clearance and vascular mixing.

SENSITIVITY ANALYSIS

The sensitivity of the model to changes in various variables was examined by introducing variability into one variable at a time: the variables examined were cardiac output, cerebral blood flow, systemic distribution volumes, lung extraction and lung distribution volume. Simulations were performed with these variables set at their normal value, and at values 50% higher and 50% lower than normal (see tables 2 and 3 for actual values used). For lung extraction, simulations were performed with lung extraction at constant values of 15%, 30% and 60% rather than the usual non-linear extraction.

IMPLICATIONS FOR DOSE REGIMENS

The model was used to examine the dose requirements of propofol to achieve a given level of anaesthesia for two administration paradigms. First, the optimum duration of injection of propofol was determined by simulations for a range of durations of injections while varying the dose until a peak brain concentration of 2 mg $litre^{-1}$ was achieved in each case. The required dose, time to peak arterial and brain propofol concentrations, and magnitude of peak arterial propofol concentrations were related to duration of injection. Second, to mimic the clinical practice of infusion with titration to a given anaesthetic end-point, the model was used to simulate infusions of propofol at rates of 50, 100 and 200 mg min^{-1} with administration stopped when a brain concentration of 2 mg $litre^{-1}$ (nominally loss of consciousness) was achieved. For each administration rate, the total dose administered at the time of the end-point, time that end-point was reached and resulting time course of brain concentrations predicted by the model were recorded. These data were also compared with data in humans of Peacock and colleagues[7 8] and Stokes and Hutton.[9]

Results

A TYPICAL OUTPUT OF THE MODEL

Arterial and brain concentrations of propofol expected after bolus and infusion regimens for the normal cardiac output state are shown in figure 1. It is apparent that arterial concentrations of propofol are relatively transient, particularly after bolus administration. For the same dose, the infusion regimen delayed the onset of anaesthesia rather than affecting its depth, compared with the bolus. Thus

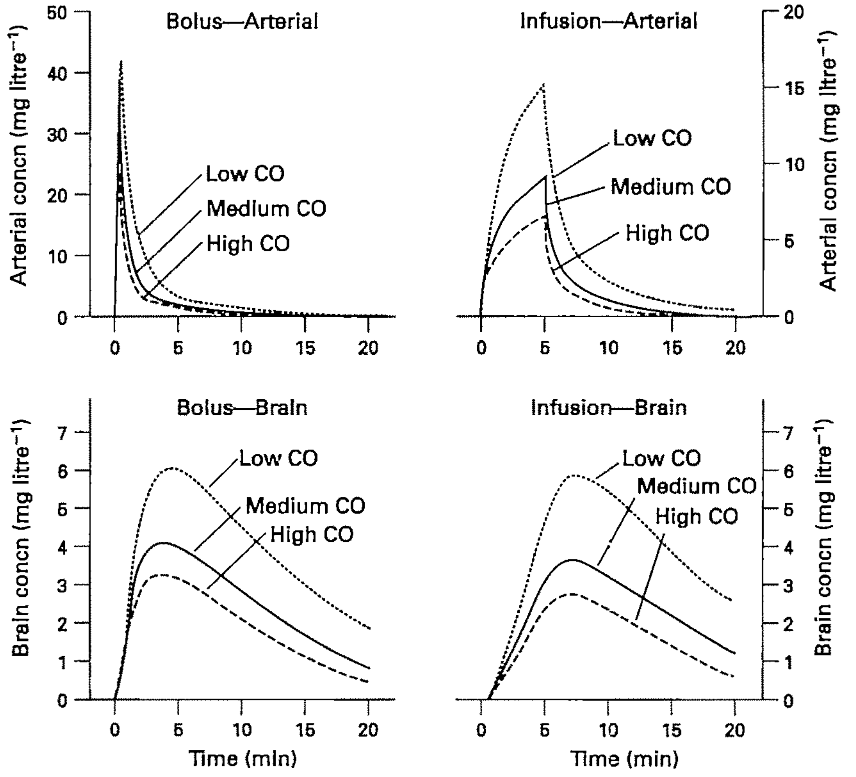

Figure 1 Typical outputs of the model, also showing the sensitivity of the model to changes in cardiac output (CO). Data were simulated with CO at its normal baseline value (medium), and at a value 50% lower (low) or 50% higher (high) than normal.

Table 1 Structural analysis. Analysis of the effect of removing various components of the model on the peak concentration in arterial blood and brain, time of onset of anaesthesia, peak level of anaesthesia as a percent of normal and time of this peak, and total duration of anaesthesia. CBF=Cerebral blood flow

Analysis	Peak arterial (mg litre^{-1})	Peak brain (mg litre^{-1})	Onset time (min)	Peak effect (% normal)	Peak time (min)	Duration (min)
Bolus						
Normal	38.03	4.07	1.15	100	3.9	12.6
No CBF changes	38.14	4.49	1.05	110	3.4	9.7
No recirculation	37.83	2.47	1.45	61	2.8	4.05
No hepatic clearance	38.14	4.15	1.15	102	4.1	15.05
No vascular mixing	39 56	3.80	1.15	93	3 8	11.65
Infusion						
Normal	9.00	3.66	3.5	100	7.1	12 4
No CBF changes	9.00	4.53	3.25	124	6.6	10.6
No recirculation	5.95	2.77	3.85	75	5.9	5.95
No hepatic clearance	9.39	3.80	3.45	104	7.5	15.45
No vascular mixing	9.08	3.68	3.45	101	7.1	12.5

infusion of the same dose as used for the bolus caused a 10% decrease in the maximum depth of anaesthesia, but only a 1.5% reduction in duration of anaesthesia. However, the time of onset of anaesthesia was increased from 1.15 to 3.5 min, while the time of maximum depth of anaesthesia was increased from 3.9 to 7.1 min.

STRUCTURAL ANALYSIS

The structural analysis is summarized in table 1. Removing propofol-induced reductions in cerebral blood flow from the model caused insignificant changes in peak arterial concentrations for either dose regimen. This suggests that the contribution of recirculated propofol from the brain to arterial concentrations is low when cerebral blood flow is a small fraction of cardiac output (as in sheep). However, the peak brain concentration was 10–12% higher, onset of anaesthesia earlier and duration of anaesthesia 15–25% less in the absence of propofol-induced reductions in cerebral blood flow. This taller but narrower peak in brain concentrations is entirely consistent with, and characteristic of, the higher average flow in this situation.[10]

The effect of removing recirculation, effectively making the model show the first-pass passage of the injected peak of propofol, differed with the dose regimen. The peak arterial concentration was unaffected by the absence of recirculation for the bolus regimen, but was significantly lower for the infusion. Without recirculation peak brain concentrations of propofol were 61% and 75% of normal for the bolus and infusion, respectively, but duration of anaesthesia was substantially shorter than normal.

Removing hepatic clearance from the model caused only a minor increase in peak arterial propofol concentrations, and its effect was similar for both dose regimens. Peak brain concentrations were altered by less than 4%, but the absence of hepatic clearance decreased the rate of elution of propofol from the brain and prolonged the duration of anaesthesia.

Removing the vascular mixing component of the model resulted in only minor changes in the time course of anaesthesia, but was more important for the bolus regimen.

SENSITIVITY ANALYSIS

Altering cardiac output had a profound effect on both arterial and brain concentrations of propofol

Table 2 Sensitivity analysis for bolus dose. throughout the induction period for both dose regimens (fig. 1, tables 2 and 3). A four-fold *increase* in cardiac output (2.8 to 8.4 litre min^{-1}) produced a *decrease* in peak arterial and brain concentrations (to 78% and 54% of the low value for the bolus, and to 42% and 47% for the infusion, respectively). However, the time of these peak values were within 15% of each other, with the exception of the time to peak arterial concentrations after the bolus dose (from 0.5 to 0.3 min).

Altering cerebral blood flow had a minimal effect on arterial concentrations and, in comparison with cardiac output, had an opposing effect on brain concentrations of propofol. A four-fold *increase* in cerebral blood flow produced an *increase* in brain concentrations after the bolus to 196% of the low value, and this increase was also substantial (172%) for the infusion. However, higher peak brain concentrations were not associated with longer durations of anaesthesia, as the decline in brain concentrations was also more rapid.

The presence or absence of recirculation was found to substantially alter the time course of both arterial and brain propofol concentrations (table 1), but the model was less sensitive to the actual magnitude of the distribution volumes of the tissue pools that affected the extent of recirculation (tables 2 and 3). Larger tissue pools decreased peak arterial concentrations significantly for the infusion regimen, but the bolus was less affected. However, duration of anaesthesia was decreased to a similar extent for both regimens (15–20%).

Of more importance to the propofol concentrations achieved after both dose regimens was the magnitude of lung extraction (tables 2 and 3). While this is markedly non-linear in sheep,[1] this simulation showed what could be expected if extraction was set over a range of constant values. The extent of lung extraction greatly altered the magnitude of arterial concentrations. Peak arterial values decreased from 34.3 to 16.1 mg litre^{-1} for the bolus, and from 8.65 to 3.37 mg litre^{-1} for the infusion as lung extraction increased. Secondary to these altered arterial concentrations, brain concentrations also decreased with increasing lung extraction. At the highest value of lung extraction, brain concentrations were sufficiently low that propofol produced no anaesthesia. However, at anaesthetic concentrations, lung extraction of propofol is relatively low[1] and it is unlikely that high values of lung extraction would be encountered when it is used as an induction agent.

As the role of the lung in the metabolism of propofol is important, it may be expected that distribution of propofol into the lungs may also have a substantial effect on concentrations of propofol. However, the effect was relatively small for the infusion regimen, while more pronounced for the bolus (tables 2 and 3). In particular, the distribution volume of the lung had a clear role in attenuating peak arterial concentrations for this regimen.

IMPLICATIONS FOR DOSE REGIMENS

Effect of rate of administration

The effects of changes in the rate of injection on dose requirements to reach a peak brain concentration of 2 mg litre^{-1} are shown in figure 2A. The dose was minimized when propofol was administered over approximately 2 min, with peak brain concentrations reached at approximately 4.5 min. More rapid injection had little effect on the time to achieve peak concentrations in the brain (fig. 2B) but was associated with a large increase in peak arterial concentrations (fig. 2C). In general, peak brain concentrations (and therefore maximum depth of anaesthesia) lagged behind the end of the injection by approximately 3 min for these rapid injections, but this was reduced to approximately 2 min for the slower injections.

The effects of changing the rate of injection of a given dose (100 mg) are shown in figure 3. Decreasing the duration of injection to less than 1 min produced little effect on peak brain concentrations, but was accompanied by large increases in arterial concentrations.

For infusion with titration to an end-point, the

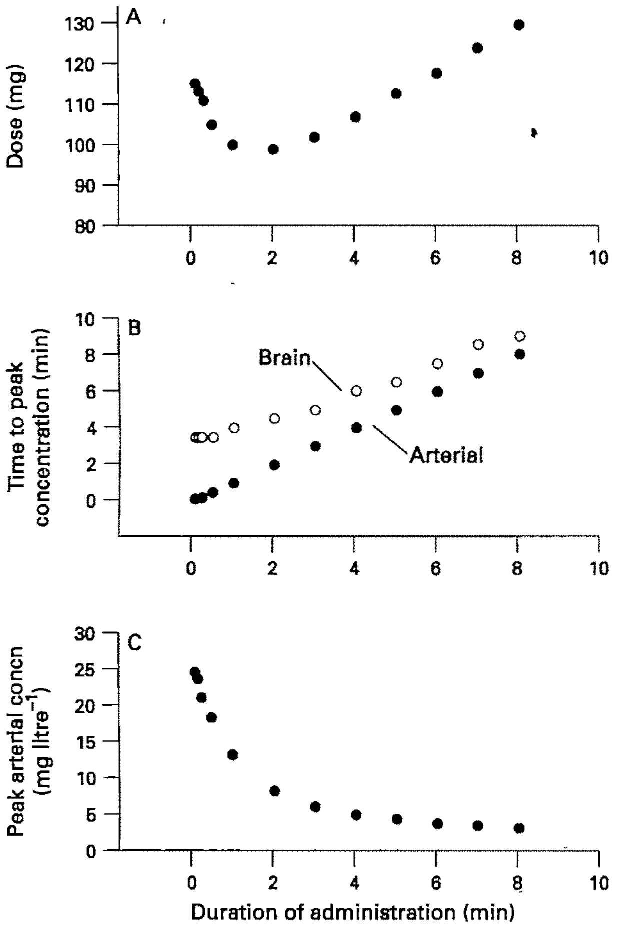

Figure 2 Effects of duration of administration on: (A) dose required to reach a peak brain concentration of propofol of 2 mg litre^{-1}; (B) concurrent times to reach peak concentrations in arterial blood (●) and brain (○); and (C) concurrent peak arterial concentrations achieved.

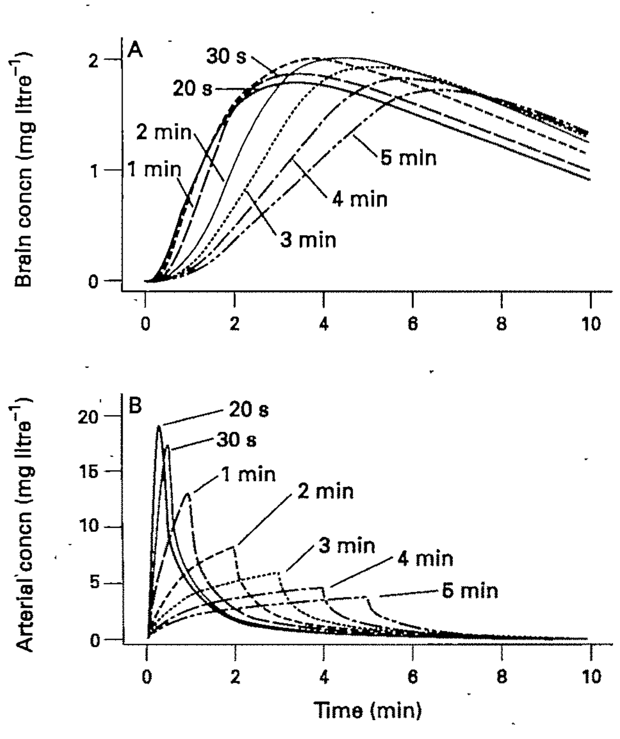

Figure 3 Simulation of administration of propofol 100 mg at different rates of injection on the time course of concentrations in the brain (A) and arterial blood (B).

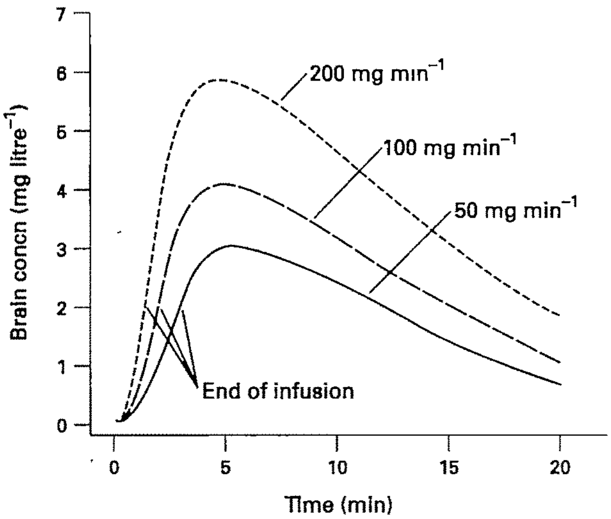

Figure 4 Titration by infusion. Simulation of the time course of brain concentrations of propofol when administered at different infusion rates, with infusions ceased when a brain concentration of 2 mg litre^{-1} was reached.

profile of brain concentrations at different infusion rates is shown in figure 4. Note that the peak brain concentrations occurred approximately 3 min after cessation of the infusion, and that the highest infusion rate was associated with peak brain concentrations 2–3 times higher than those chosen as the end-point. The corresponding total doses administered and the time of onset of anaesthesia are shown

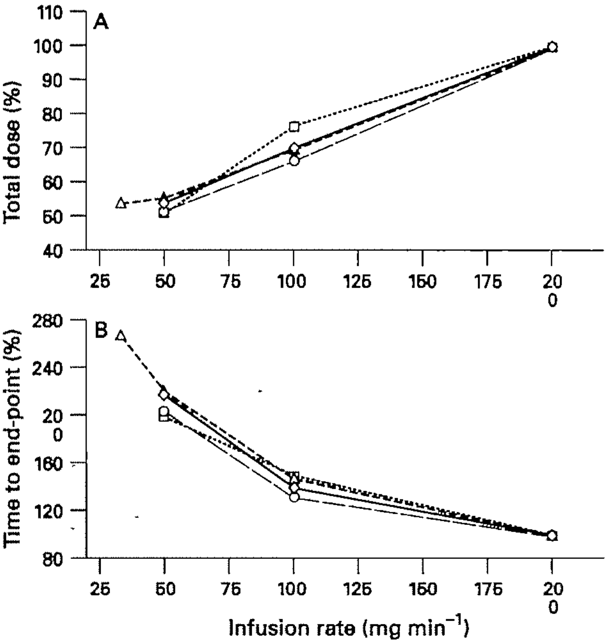

Figure 5 Comparison of the predictions of the model with data from humans on the influence of decreasing the infusion rate of propofol when titrating to a given anaesthetic end-point. Total administered dose (A) and time of onset of the anaesthetic end-point (B) are shown for the model based on data in sheep (solid line) and for the data in humans of Stokes and Hutton (□),[9] Peacock and colleagues 1990 (○)[7] and the young patient group of Peacock and colleagues 1992 (△).[8] As different anaesthetic end-points were used in each study, the total dose and time to end-point are expressed as a percentage of the fastest infusion rate. Data for the old patient group from the latter study could therefore not be presented in this format, as no 200 mg min^{-1} dose was given.

in figure 5. Lower infusion rates were associated with a slower onset of anaesthesia, lower total doses at the point of onset of anaesthesia and lower peak brain concentrations after cessation of administration.

Discussion

The principal purpose of this model was to consolidate experimental data from a chronically instrumented sheep preparation.[2 3] It is important to remember that the model has therefore been validated extensively against a comprehensive *in vivo* data set[1] comprising measurements of blood flows and propofol concentrations in several sites, rather than the more traditional single set of arterial or venous blood concentrations. This greatly increases the physiological "fidelity" of the model.

MODEL ANALYSIS

Most features of the model had a significant influence on the output of the model, and their inclusion would seem reasonable on more than theoretical grounds. Interestingly, the value of some features depended on the administration regimen. In particular, the bolus regimen was influenced by the vascular mixing and lung kinetic components, highlighting the crucial role of these systems as "capacitors" or stores of drug after rapid injection.[11 12]

Two of the features of the model were analysed for mechanistic reasons only. Recirculation of drug is clearly unavoidable, and is an integral part of the induction process (table 1). However, it is surprising to what extent first-pass passage of the injected peak contributes to induction of anaesthesia (approximately 60% of the peak anaesthesia and 33% of its duration). Recirculation of drug is often thought to occur rapidly (seconds rather than minutes), a situation that is not consistent with drugs such as propofol with high distribution volumes in tissues. The vascular mixing component of the model is compatible with our previous experimental observations of injection site to pulmonary artery transit[13] and contributes to the accurate description of kinetics after very rapid injections.

The remaining features of the model have more physiological significance, and will be discussed in turn.

DOSE AND INJECTION RATE

Rapid rates of injection of a dose of propofol achieved little in terms of increased depth of anaesthesia, but hastened its onset at the expense of markedly increased peak concentrations in the arterial system (fig. 2). While the significance of high initial concentrations in arterial blood vessels is not clear, arterial and venous dilatation are major contributors to hypotension during induction with propofol and may relate to direct exposure to vascular smooth muscle.[14–16] It is probably this effect that produces an increased incidence of hypotension with propofol compared with thiopentone, as both agents have a similar effect on myocardial contractility.[17]

For a given dose of propofol, very rapid injections appear to produce a peak in arterial concentrations that is too transient to fully load the brain with propofol (fig. 2), while for very slow injections peak brain concentration can be attenuated by metabolism and redistribution of the dose before the time of the peak (fig. 3). Consequently, there appears to be an optimal duration of injection of a given dose of propofol (2 min) for maximum depth of anaesthesia. Thus the model predicts that there are two possible benefits of administration of propofol over 2 min rather than the more traditional bolus—a direct dose-sparing effect and reduced peak arterial concentrations which may have a haemodynamic advantage.

When titrating to an anaesthetic end-point, it has been shown previously that slower rates of infusion of propofol reduce the total dose administered.[7–9] It has been speculated that this may be because of more propofol being "in transit" between the injection site and brain at higher infusion rates,[18] and this is confirmed in figure 4. For higher infusion rates, brain concentrations increased rapidly and continued to increase prodigiously after cessation of infusion, because of the greater mass of propofol stored in venous blood and lungs that had yet to reach the brain. Slower infusion rates were associated with slower increases in brain concentrations with better titration against the end-point, and minimized this "overshoot" in brain concentrations. The dose-sparing effect of the slower infusion is an illusion in the sense that although less propofol was used to reach the end-point, the total amount of anaesthesia produced (the AUC of the brain concentrations), particularly after cessation of infusion, was also significantly less. Regardless, there are considerable benefits in using the slower rate in that it reduces the profound increase in depth of anaesthesia after the desired end-point.

CARDIAC OUTPUT

Cardiac output was an important factor affecting induction of anaesthesia, with increased cardiac output decreasing depth and duration of anaesthesia. While the initial effect of cardiac output would be expected on the basis of indicator dilution principles before recirculation,[13] it is surprising that it persisted throughout the study. This is likely to be a result of the influence of cardiac output on tissue distribution in the model, which is reinforced by an increasing number of studies,[19–22] and is a feature of other physiological models.[23 24] Indeed, this growing evidence suggests that cardiac output may be a clinically significant determinant of the induction process, and a widely neglected pharmacokinetic variable.

Cardiac output can be subject to large changes *in vivo* because of factors such as age, anxiety or co-administration of other drugs, and the model predicted that these changes would also influence induction of anaesthesia with propofol. This is confirmed to some extent by the recent work suggesting that co-administration of esmolol, a beta blocker, provided a large dose-sparing effect on propofol requirements during induction of anaesthesia,[25] a phenomenon consistent with the cardiac output lowering effect of esmolol. The contribution of this process to the dose-sparing effect observed with other co-induction agents is as yet unknown.

CEREBRAL BLOOD FLOW

Cerebral blood flow was also a substantial determinant of the induction process, with increased cerebral blood flow increasing depth of anaesthesia, but causing relatively small changes in its duration. The fact that propofol reduces cerebral blood flow by up to 50%, thereby altering its own kinetics in the brain, was a significant feature of the induction process resulting in a lower mean cerebral blood flow and prolongation of the duration of anaesthesia by almost 3 min. There have been few experimental studies to confirm the role of cerebral blood flow in the induction process, although we have confirmed the cerebral kinetic implications of altered cerebral blood flow for propofol.[26] Cerebral blood flow would be expected to change *in vivo*, particularly in response to changes in carbon dioxide tension in the blood (e.g. after hyperventilation and by states such as anxiety), and the model predicts that these changes would also influence induction of anaesthesia with propofol.

TISSUE DISTRIBUTION VOLUMES

As for thiopentone,[27] distribution into systemic tissues contributed to the decline in arterial concentrations of propofol (tables 2 and 3), although clearance by the lung was also a significant factor for lower doses of propofol in this species. As expected, smaller tissue volumes increased the rate of recirculation of propofol, but the model was relatively insensitive to changes in the magnitude of the tissue distribution volumes. These volumes are a composite term incorporating the physical volumes of these tissues, their lipid content, extent of blood and tissue protein binding, and partitioning of ions across pH gradients.[28] The changes simulated were relatively large—it is not clear to what extent these changes can be accounted for *in vivo* by alterations in factors such as protein binding of propofol within and between individuals. For example, a four-fold increase in apparent tissue volume would require a decrease in the fraction bound in blood from 90% to 22.5%.

LUNG KINETICS

While the lung kinetics of propofol were shown to be important factors in the induction process, the significant kinetic process was not distribution, but metabolism, particularly for lower doses. Both processes have been demonstrated to occur in the lungs for a variety of drugs.[29] Unfortunately, current double indicator methods for studying lung kinetics after bolus administration[12 30] are poor at differentiating between metabolism and distribution. Extensive, saturable conjugation of phenol by the lungs after bolus administration has been identified in rats, however,[31 32] and provides support for such a mechanism underlying the observed extraction of the phenol, propofol, after rapid administration to sheep.

CLEARANCE

In this study, clearance via the lungs was the only significant route of elimination for propofol during induction. Although hepatic clearance of propofol is sheep is large (approximately 87% extraction[4]), it had a relatively small effect on the induction process. By removing hepatic clearance, onset time and peak depths of anaesthesia were changed little, although duration of anaesthesia was increased by 2.5–3 min. This is consistent with reports of declines in propofol blood concentrations in anhepatic individuals.[33] Thus even large variations in hepatic enzyme efficiency caused by processes such as enzyme induction or inhibition would be expected to have minimal effects on the induction process.

IMPLICATIONS FOR HUMANS

Clearly, the basic mechanisms of kinetics and dynamics discussed in this article can be studied only in animals. The mechanisms described are valid for sheep, for which the variables of the model were estimated from an extensive *in vivo* data set. The technique of examining arterio-jugular gradients of drugs may be used to re-parameterize the model for humans,[34] particularly if cerebral blood flow is measured concurrently.[35] There is some evidence that the changes needed are not great with respect to initial bolus kinetics. The general size of the heart–lung system and cardiac output of a 50-kg sheep are similar to those of a 70-kg human, although the fraction of cardiac output reaching the brain is much reduced.[36] However, as relative perfusion of the brain is comparable with humans and cerebral blood flow responses to drugs in sheep have been found to be similar to those in humans,[2 37] the time course of the brain concentrations is also similar. The evidence for substantial lung extraction of propofol in humans is ambiguous, although it should be noted that clearance of propofol in humans often exceeds the expected liver blood flow. The data of Major and colleagues[38] showed large gradients across the lung, while Gray and colleagues[33] reported no gradient in anhepatic individuals. It is evident, however, that this extraction is relatively low at blood concentrations of propofol used clinically to induce anaesthesia, and so inter-species differences are likely to be relatively insignificant.

Despite these considerations of species differences, it is worth noting the very close agreement between the effects of the rate of propofol administration on induction dose and time to onset of anaesthesia between the current model and data in humans by different investigators (fig. 5). This suggests that the fundamental principles of distribution after bolus administration of propofol are similar between sheep and humans, and that the model, as presented, provides a valuable tool for designing further studies of induction of anaesthesia with propofol in sheep and humans. We advance the following hypotheses arising out of this work.

(1) There is little benefit in injecting propofol more rapidly than over 2 min. More rapid administration does not greatly increase the rate of induction, and potentially may increase the risk of hypotension because of high arterial concentrations.

(2) For titration of depth of anaesthesia with small bolus doses or infusion, a period of 2–3 min should be allowed between cessation of the dose and assessment of the level of anaesthesia in order to ensure the maximum depth of anaesthesia has been achieved.

(3) The effect of many clinical scenarios on propofol dose requirements (such as anxiety, hyperventilation, extremes of body weight and co-administration of other drugs) can be interpreted in terms of their primary effect on cardiac output and cerebral blood flow. Thus selection of a dose regimen for propofol may be best determined by consideration of these two factors.

Overestimation of low cardiac output measured by thermodilution

J. P TOURNADRE, D. CHASSARD AND R. MUCHADA

Summary

We have investigated the influence of a cold water bolus (CWB) injection on overestimation of cardiac output (CO) in low CO states in anaesthetized dogs. CO was measured using three methods: (1) thermodilution (TD), (2) electromagnetic (EM) flow meter placed on the pulmonary artery and (3) transoesophageal echo-Doppler (OD) placed on the descending aorta. Measurements of CO were obtained before (steady state) and after induction of a low CO state with thiopentone 5 mg kg^{-1} i.v. After CWB injection, mean CO measured by EM and OD increased by 26% and 27%, respectively ($P<0.05$) during steady state, and by 85% and 75% ($P<0.05$) during the low CO state. This transient increase was produced by an increase in stroke volume, while heart rate did not change. Frank Starling's law may explain this variation by a sudden increase in preload produced by CWB injection. These results indicate that thermodilution overestimated CO during low CO states when CWB injection was used. (*Br. J. Anaesth.* 1997; **79**: 514–516).

Key words
Heart, cardiac output. Measurement techniques, cardiac output. Measurement techniques, thermodilution. Measurement techniques, transoesophageal Doppler. Measurement techniques, flowmetry. Dog.

Several methods have been used to measure cardiac output (CO) in humans. The thermodilution method (TD), described initially by Fegler,[1] has been used for 20 yr since its development with the catheter described by Swan and Ganz.[2] Several studies have demonstrated good overall agreement between TD and other methods estimating CO. However, several studies have shown that the TD method overestimates CO in the low range.[3–5] This was explained by heat loss during measurement.[3]

In our clinical anaesthetic practice, we observed in patients in whom CO was recorded simultaneously by TD and transoesophageal echo-Doppler (OD), an increase in CO measured by OD, immediately after injection of an iced water bolus. Therefore, this study was designed to investigate the effect of an iced temperature injectate on CO measured by TD, OD and by an electromagnetic (EM) flow meter placed on the pulmonary artery of anaesthetized dogs during normal and low CO states.

Materials and methods

After approval from our institutional Animal and Care Committee, six dogs (weight 18 (SD 5) kg) were anaesthetized with thiopentone 5 mg kg^{-1}, vecuronium 0.08 mg kg^{-1} and phenoperidine 0.015 mg kg^{-1}. The trachea was intubated and the lungs ventilated mechanically (Bird Mark 8, Products Corporation, Palm Springs, CA, USA) at an FI_{O_2} of 1, ventilatory frequency 20 bpm and tidal volume 10 ml kg^{-1}. Anaesthesia was maintained with phenoperidine 0.02 mg kg^{-1} h^{-1} and vecuronium 0.04 mg kg h^{-1}.

A Swan–Ganz catheter was inserted into the pulmonary artery via the right external jugular vein under x-ray control (7F diameter, Edwards Laboratories, Irvine, CA, USA). Thermodilution CO was measured using triplicate injections of 5 ml of 5% dextrose at 2 °C (cold water bolus (CWB)) during end-expiration.

A 12-mm EM flow probe (In Vivo Metric, Healsburg, CA, USA) was placed around the pulmonary artery after dissection of the pulmonary trunk via a left-sided thoracotomy. Pulmonary blood flow (PBF) was measured continuously with an EM blood flow meter (FM 501, Carolina Medical Electronics, King, NC, USA).

A special echo-Doppler probe, described previously,[6] was used to measure aortic blood flow (ABF) using a transoesophageal echo-Doppler (OD) ultrasound method (Dynemo 3000, Sometec, Paris, France). ABF, PBF, ECG and heart rate (HR) were recorded simultaneously and continuously before, during and after CWB injection.

Measurements were made with both continuous methods (PBF, ABF) after 15 min of steady state following surgical preparations and were repeated after injection of thiopentone 5 mg kg^{-1} i.v. to obtain a low CO state.

Instantaneous blood flow variations were measured by EM flow meter and OD methods during CWB injection. These measures were integrated by planimetry to calculate the average stroke volume (SV) on seven cardiac cycles. These

were identical to cycles sampled during inscription of the TD curve.

Data are expressed as mean (SD) and were compared by Wilcoxon's test between the two states and by one-way analysis of variance (ANOVA) for haemodynamic data obtained by the different methods. Results were considered statistically significant at $P<0.05$.

Results

Results are summarized in table 1.

In all cases injection of thiopentone 5 mg kg^{-1} produced a decrease in HR and SV. For all measurement techniques there was a decline in CO after thiopentone ($P<0.05$). HR remained unchanged throughout the course of injection of the CWB using the TD method. CO values obtained by TD were higher than those obtained by the two other methods ($P<0.05$). The differences recorded with the other methods were more important during low CO states.

Table 1 Mean (SD) pulmonary blood flow (PBF), aortic blood flow (ABF) and cardiac output (CO) (measured by the thermodilution method) at steady state and after injection of thiopentone 5 mg kg^{-1} (low CO state). *$P<0.05$ *vs* before injection of the cold water bolus (CWB);.†$P<0.05$ *vs* steady state

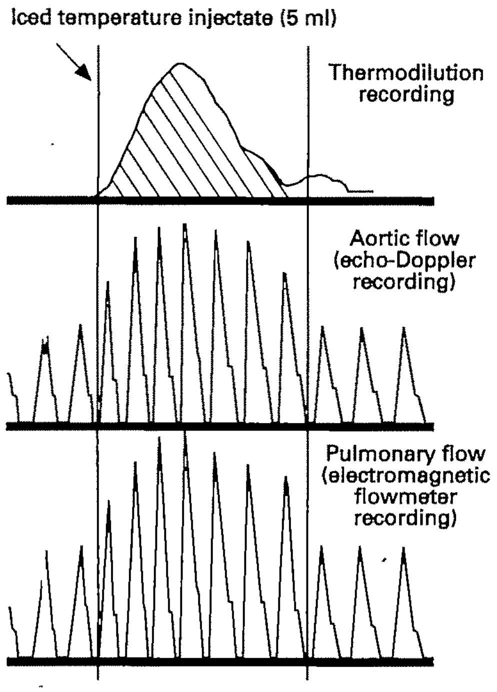

Figure 1 Effect of a cold water bolus (iced temperature) injection on stroke volume measured in the descending aorta and pulmonary artery in a dog with a low cardiac ouput.

CWB injection induced significant increases in PBF and ABF ($P<0.05$) (fig. 1). These increases were found in the two states but were proportionally more important during the low CO state.

Differences between the results of TD and those of pulmonary flow meter and aortic OD obtained after injection of CWB were not statistically significant. After CWB injection, CO, measured using EM and OD, increased by 26% and 27%, respectively, during steady state ($P<0.05$), and by 85% and 75% during low CO state ($P<0.05$).

Discussion

Data from previous studies showed that the TD method overestimated measurement of CO in patients with low CO states. This could explain the weak correlation between measurements by TD and other methods, such as the Fick method, during low CO conditions,[7 8] dye dilution techniques[9] and EM flow meter on the pulmonary artery.[10] These studies attributed differences to heat loss under conditions of low flow.[3–5 11–13] Our study did not evaluate this phenomenon during high output states as previous studies found a good correlation between TD and other methods under these conditions.[2 3]

In the course of the two CO states evaluated in our study (steady and low CO state), TD overestimated CO values compared with EM flow meter and OD (note that these two methods are performed in two different anatomical sites, the pulmonary artery and descending aorta, respectively). This was more significant in the presence of a low CO state. ABF was lower by 13–17% compared with PBF under all conditions. This can be explained by the fact that measurements at this level of the aorta do not take into account blood flow to the upper extremities, head, bronchial tubes and cardiac areas.

The increase in aortic flow was lower than that of pulmonary flow (75% and 85%, respectively, $P<0.05$) during the low CO state. This may reflect a septal shift in response to substantial increases in right ventricular end-diastolic volume that might transiently decrease left ventricular end-diastolic volume because of the restrictive effects of the pericardium. Thus aortic flow would be lower than pulmonary flow.

We found that CO, when measured by EM or OD, increased in all cases after administration of CWB injection. This transient increase was produced by an increase in SV over several cardiac cycles, while HR remained unchanged. During rapid injection of CWB into the right atrium, a transient increase in CO could increase SV by increasing preload. Frank Starling's law may explain this variation by a sudden increase in preload after CWB injection. This also explains why the phenomenon is more significant at low compared with normal CO states.

The increase in SV after injection of the CWB occurred without a change in HR. This may have resulted from the use of thiopentone. Its effect on the autonomic nervous system[14] prevents the sinus bradycardia caused by CWB injection described by Harris and colleagues[15] and Nishikawa and Dohi[16 17] under similar conditions. Because CO=SV×HR, a decrease in HR may balance the increase in SV. This may explain the good correlation between CO determination with TD and other methods, even in low CO states.[7,18–20] However, when HR is unchanged, especially in low CO states, the transient increase in SV could be responsible for discrepancies between TD and other methods of measurement of CO.[3,8,11,21]

With the TD method,[19] CO output is measured in the course of the first cardiac cycles after injection of the CWB. We found that SV increased after injection of the CWB compared with basal values. Thus the calculated output is overestimated. It is remarkable to note that when we measured outputs by EM and OD after CWB injection, we found values close to those obtained by TD during steady state or low CO. One can therefore estimate that, in our study, CWB injection induced the major part of the overestimation. The potential human implications of these findings need to be verified.

We used iced temperature injectates rather than room temperature injectates, as first described by Swan and Ganz.[2] To eliminate the influence of temperature induced by cardiac reflexes,[16,17] a study should be performed under the same conditions.

Accurate measurement of CO is an important goal in the management of anaesthetized or critically ill patients with compromised cardiac function. Our findings showed that thermodilution overestimated CO during low CO states when iced temperature injectates were used. This suggests that other non-invasive methods are necessary to determine CO in patients with low output states.

Effect of temperature on the solubility of desflurane, sevoflurane, enflurane and halothane in blood

G. G. LOCKWOOD, S. M. SAPSED-BYRNE AND M. A. SMITH

Summary

We have investigated the effect of temperature on the blood-gas solubility of desflurane, sevoflurane, enflurane and halothane. Blood was equilibrated with gas mixtures of known composition in open cuvette or closed flask tonometers over a temperature range of 29–39 °C, and the concentration of each anaesthetic in blood was measured at 37 °C by repeated headspace analysis using a gas chromatograph. Solubility increased by 5.4% of the solubility at 37 °C for each degree that equilibration temperature was reduced. This result was true for all anaesthetics in all blood samples, and is in keeping with results for other volatile anaesthetics. (*Br. J. Anaesth.* 1997; **79**: 517–520).

Key words

Anaesthetics volatile, desflurane. Anaesthetics volatile, enflurane. Anaesthetics volatile, halothane. Anaesthetics volatile, sevoflurane. Temperature, solubility. Solubility, temperature.

Measurement of anaesthetic partial pressure in blood is affected by temperature because of a concomitant change in solubility. The most direct solution to this problem is to measure every sample at the temperature at which it was sampled, but it is inconvenient to measure several samples at different temperatures and a correction factor is commonly used instead. Measurements of solubility at different temperatures, from which such correction factors may be derived, have been published for halothane, enflurane, isoflurane and older agents,[1–4] but we are not aware of similar publications for newer anaesthetics. We have therefore measured the effect of temperature on blood solubility for desflurane and sevoflurane, but have included halothane to confirm that the results of our method agree with standard values, and enflurane to confirm the observation that it is different from other volatile anaesthetics.[4]

Methods

After Ethics Committee approval, we obtained 25 ml of blood from healthy volunteers and patients undergoing major surgery. Two methods were used to prepare samples. In the first studies, 5-ml aliquots were placed in the cuvette of an Instrumentation Laboratory IL 237 tonometer and equilibrated in a gas flow of 200 ml min^{-1} of air containing a single agent (approximately 3% desflurane or 1% sevoflurane) at different temperatures over a range of 29–39 °C. Blood temperature within the cuvette was measured by a bead thermistor (Kanthal Tempmaster). At the end of the equilibration period (15 min at stable temperature) samples were obtained from the tonometer gas outflow and analysed in a gas chromatograph (GC, see below). The tonometer was opened and two 2-ml samples of blood were obtained consecutively into a 2.5-ml gas-tight syringe (SGE, Milton Keynes, UK) and transferred into 5-ml glass vials (actual volumes 4.77 (SD 0.03) ml) which were closed with screw caps fitted with Teflon-faced septa. In the later experiments we tonometered the entire blood sample in a closed glass flask. The flask was flushed with a gas mixture containing approximately 1% each of sevoflurane, enflurane and halothane (desflurane could not be separated easily and was not included) and then sealed using a cap with a Teflon-faced silicone septum. It was fitted into a weighted jacket to lie submerged on rotating rollers in a water bath. Every 15 min during equilibration the septum was pierced to allow manometric pressure measurement. If positive pressure was found it was vented and the process repeated, but if not samples were obtained. Two separate samples of the flask headspace were first obtained by puncturing the septum, aspirating a gas sample and injecting it into the GC. Blood was obtained by inverting the flask and again sampling through the septum, and 2 ml were transferred into each of two 5-ml vials. The flask septum was replaced with a new one, the water bath thermostat adjusted and the process repeated so that each sample was equilibrated at four or five temperatures from 28 to 39 °C.

Blood samples were analysed by a method which determines the total content of each anaesthetic in blood when it was originally placed in the vial. Blood-gas solubility was derived from this because

the initial anaesthetic partial pressure in the tonometer was known. Blood-gas solubility at 37 °C was also derived in this analysis.[5] The vials containing samples of blood from the tonometer were agitated in a water bath at 37 °C for 15 min to equilibrate the anaesthetic between the blood and gas phases. The headspace gas of each vial was sampled through the septum and injected into the GC. The vial was then opened, 1 ml of blood aspirated into the 2.5-ml syringe (taking care to prevent bubbling) and transferred to a clean vial and capped. This second, new vial was agitated at 37 °C for 15 min and the headspace analysed in the same way.

All gas analysis was performed in duplicate. Gas was aspirated into a 100-μl gas-tight syringe (SGE) and flushed through the 20-μl loop of a six-way valve (Valco) on the inlet of the GC (Pye Series 204). The carrier gas was nitrogen flowing at 30 ml min^{-1}. A 0.9-m glass column (2 mm id) packed with 3% OV-17 on GasChrom Q and maintained at 125 °C was used when a single agent was being measured (giving a retention time of approximately 30 s). A 1.5-m column, packed similarly, was maintained at 60 °C with a carrier flow of 15 ml min^{-1} to aid separation of multiple agents (retention time up to 2 min). Anaesthetic was detected by a flame ionization detector operating at 175 °C. Output from the GC was collected by a Perkin-Elmer LCI-100 integrator.

The blood-gas solubility coefficient at 37 °C (λ_{37}) was derived by considering the amount of anaesthetic in the second vial before and after equilibration.

$$\text{Content before equilibration} = 1\ \text{ml} \times P_1 \times \lambda_{37} \tag{1}$$

where P_1 = partial pressure (expressed as a fraction of ambient pressure) of anaesthetic in the first vial after equilibration and 1 ml = volume of blood.

$$\begin{gathered}\text{Content after equilibration} = \\ 1\ \text{ml} \times P_2 \times \lambda_{37} + 3.77\ \text{ml} \times P_2\end{gathered} \tag{2}$$

where P_2 = partial pressure of anaesthetic in the second vial after equilibration and 3.77 ml = volume of air in the headspace.

No anaesthetic is lost from the vial during equilibration so these expressions are equal, and so

$$\lambda_{37} = \frac{3.77 P_2}{P_1 - P_1} \tag{3}$$

The amount of anaesthetic in the vial at the end of the first equilibration can now be calculated.

$$\begin{gathered}\text{Content of first vial after equilibration} = \\ 2\ \text{ml} \times P_1 \times \lambda_{37} + 2.77\ \text{ml} \times P_1\end{gathered} \tag{4}$$

This amount of anaesthetic was contained in 2 ml of blood in equilibrium with the gas mixture in the tonometer.

$$\begin{gathered}\text{Content of first vial before equilibration} \\ = 2\ \text{ml} \times P_0 \times \lambda_{\text{tono}}\end{gathered} \tag{5}$$

where P_0 = partial pressure of anaesthetic in the tonometer gas flow and λ_{tono} = blood-gas solubility coefficient at the temperature of equilibration.

Equating (4) and (5), and re-arranging we obtain:

$$\lambda_{\text{tono}} = \frac{2P_1 \times \lambda_{37} + 2.77 P_1}{2P_0} \tag{6}$$

If blood is equilibrated in the tonometer at 37 °C then $\lambda_{\text{tono}} = \lambda_{37}$ and it is possible to rearrange equation (6) to calculate P_0:

$$\text{Calculated } P_0 = P_1 \left(1 + \frac{2.77}{2\lambda_{37}}\right) \tag{7}$$

The difference between the calculated P_0 and the directly measured P_0 is an indication of the overall accuracy of our assay.

There is a final point to consider. P_1 and P_2 refer to the partial pressures of anaesthetic within the vial. During equilibration the total pressure within the vial increases as the headspace gas is warmed from room temperature to 37 °C and saturated with water vapour. (The tonometer gas is air carrying anaesthetic, so we can neglect any exchange of respiratory gases between blood and headspace gas.) The sample aspirated into the syringe is at ambient pressure, and the anaesthetic it contains is "diluted" by expansion to this pressure. The peak recorded from the GC must therefore be increased:

$$P_{\text{vial}} = P_{\text{GC}} \frac{310}{T_{\text{lab}}} \times 1.03 \tag{8}$$

where P_{vial} = partial pressure of anaesthetic in the vial, P_{GC} = partial pressure derived from the height of the GC peak, T_{lab} = laboratory temperature (K) and 1.03 = a factor to allow for humidity (although the headspace gas contains 6% water vapour, the gas in the syringe before injection into the GC is at room temperature, so it cannot contain more than 3% water vapour). P_{vial} is therefore approximately 8% greater than P_{GC}. Gas sampled from the flask tonometer was assumed to be saturated, but at ambient pressure, and therefore peak heights were multiplied by 1.03. Gas from the open cuvette tonometer was assumed to be dry and at ambient pressure, so no correction was made to the GC readings.

The temperature coefficient was given by the slope of the regression line of solubility coefficient on temperature, determined for each blood sample using a Microsoft Excel v4 spreadsheet. The equivalence of the two tonometers was tested by comparing the errors in measurement of sevoflurane partial pressure of blood equilibrated at 37 °C, using the Student's *t* test. Temperature coefficients of different anaesthetics were compared by non-parametric analysis of variance (Kruskal–Wallis). All statistical tests were calculated using Arcus Biomedical v6.8 on an IBM-compatible personal computer.

Results

In every sample we found a linear relationship between temperature and blood-gas solubility so that a temperature coefficient (defined as the slope of the temperature–solubility graph) could be determined

Table 1 Total number of samples, mean error of measured anaesthetic blood partial pressures of the samples equilibrated at 37°C, expressed as a percentage of the measured tonometer partial pressure and mean temperature coefficients

	Desflurane	Sevoflurane	Enflurane	Halothane
Total No. of samples (and No. at 37 °C)	59 (14)	127 (26)	101 (20)	101 (20)
Mean (SEM) error at 37 °C (% of tonometer partial pressure)	−5.8 (1.1)	−2.2 (1.4)	−5.5 (1.3)	−3.4 (1.4)
Mean (SD) temperature coefficient (°C^{-1})	−0.023 (0.003)	−0.030 (0.001)	−0.094 (0.008)	−0.100 (0.008)
Mean (SEM) $\lambda_{B/G}$ at 37 °C	0.52 (0.02)	0.62 (0.02)	1.50 (0.07)	2.00 (0.11)
Mean (SEM) temperature coefficient as a percentage of $\lambda_{B/G}$ at 37 °C (°C^{-1})	4.4 (0.2)	4.5 (0.2)	5.9 (0.5)	4.6 (0.4)

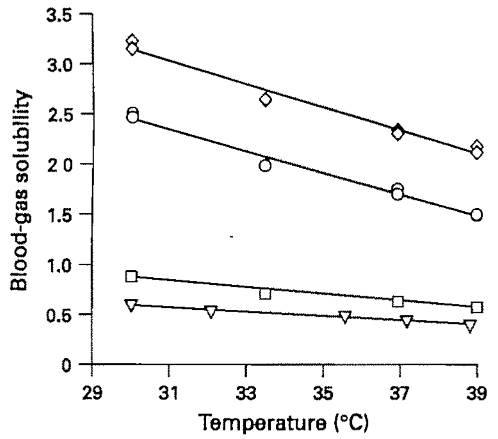

Figure 1 Typical results. Blood from one source was equilibrated with desflurane in an open cuvette. A different sample of blood was equilibrated with sevoflurane, enflurane and halothane simultaneously in a closed flask. Paired samples were obtained from the tonometers at different temperatures and regression lines are shown for desflurane (▽), sevoflurane (□), enflurane (○) and halothane (◇): the slope of the regression line is the temperature coefficient.

(fig. 1). Table 1 shows the mean error of measured anaesthetic blood partial pressures of the samples equilibrated at 37 °C, expressed as a percentage of the measured tonometer partial pressure, and summarizes our results. There were no differences in the sevoflurane results between blood equilibrated in the cuvette or flask. The temperature coefficient of enflurane, expressed as a fraction of blood-gas solubility at 37 °C, was significantly greater ($P<0.005$) than those of desflurane, sevoflurane and halothane, which were indistinguishable.

Discussion

We have used repeated headspace equilibration to determine the blood-gas coefficient. An alternative method is to vaporize a known amount of anaesthetic in a flask of known volume containing a known volume of blood. This has the advantage of being a single step technique, but the disadvantage that it is difficult to handle small quantities of liquid anaesthetic and there is no internal check for accuracy within the method. In contrast, when blood equilibrated in a tonometer at 37 °C is analysed by our method, we are able to calculate the initial partial pressure of anaesthetic at the time it was first sampled. If this calculation differs from the partial pressure of anaesthetic in the tonometer gas, it is known immediately that an error has occurred. The small deviations from the tonometer gas in our 37 °C samples justify our confidence in our methods.

We started with a commercial tonometer in which blood was equilibrated in an open cuvette. There are no concerns about pressure effects with this system, but we could not be sure of the humidity of the gas in the tonometer outflow, and the temperature of blood did not equilibrate with the water jacket and had to be measured directly. These disadvantages have been overcome in the simple, closed flask tonometer and we believe that with care we can ensure that the pressure within the flask is atmospheric, and therefore we now prefer this method.

Our two-stage headspace equilibration method determined the blood-gas coefficient at 37 °C and deduced the coefficient at other temperatures. Although it would have been simpler in principle to undertake the analysis of each 2-ml sample at its temperature of equilibration, this would have slowed the measurements greatly. At first sight, it would seem that this short-cut removes the internal check for accuracy within the method, but because one sample was equilibrated in the tonometer at 37 °C, it could be validated and its λ_{37} value assumed accurate. All samples have their blood-gas coefficient measured at 37 °C regardless of the temperature of equilibration in the tonometer and that can be compared with the validated result for the same blood sample. In practice no results were discarded on this basis.

Our results support an essentially linear relationship between temperature and solubility. In a comprehensive review of the subject, Allott and colleagues made the empirical observation that for any particular anaesthetic, the temperature coefficient was itself proportional to the logarithm of blood-gas solubility at 37 °C for that anaesthetic.[6] This relationship held over a very wide range of gases and vapours from nitrogen ($\lambda=0.014$) to diethyl ether ($\lambda=13$), but it was only one of three that could be justified on theoretical grounds. Our results suggested that, within the range of temperatures encountered clinically, a simpler relationship is adequate for modern, halogenated volatile anaesthetics: the temperature coefficient is proportional to blood-gas solubility at 37 °C. Our results went a little further. We obtained blood not only from starved, preoperative patients but also from post-prandial volunteers and patients during cardiopulmonary bypass so that for each anaesthetic we had a wide range of values of λ_{37}. For each agent studied, the effect of temperature on solubility was greatest on blood samples with the greatest solubility at 37 °C, as shown in figure 2. Logarithmic scales have been used to

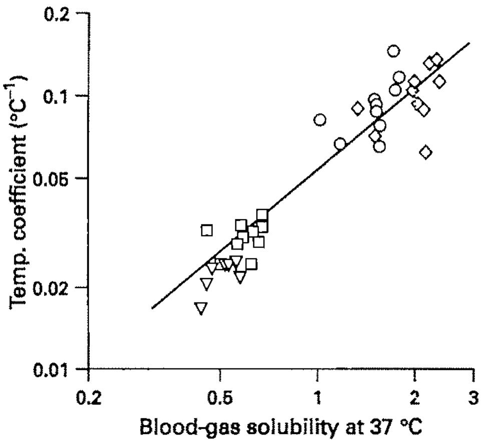

Figure 2 Dependence of the temperature coefficient on solubility at 37°C for desflurane (▽), sevoflurane (□), enflurane (○) and halothane (◇). Logarithmic axes have been used to expand the area of interest, but because the linear regression line passes through the origin, it remains straight on the logarithmic plot.

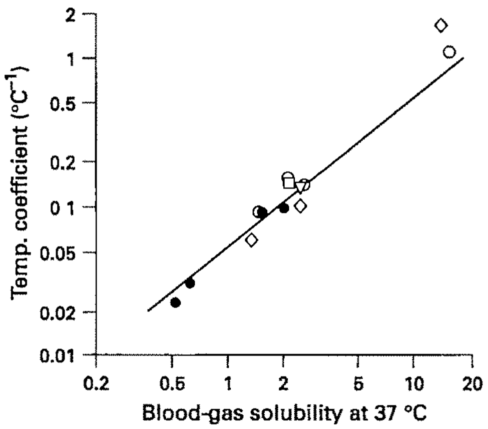

Figure 3 Dependence of the temperature coefficient on solubility at 37°C: mean results from our study and previous publications. Logarithmic axes have been used to expand the area of interest. The linear regression line derived from the data of the current study is shown: it passes through the origin so it remains straight on the logarithmic plot. ●=Present study (from left to right, desflurane, sevoflurane, enflurane and halothane); □=Han and Helrich[1] (halothane); ▽=Laasberg and Hedley-Whyte[2] (halothane); ◇=Stoelting and Longshore[3] (from left to right, fluroxene, halothane and methoxyflurane); and ○=Eger and Eger[4] (from left to right, isoflurane, enflurane, halothane, methoxyflurane).

expand the region of greatest interest, and are justified because the regression line drawn through our data passes through the origin (the sense of the temperature change has been reversed to allow a logarithmic transformation). Although the correlation is not significant for any individual anaesthetic, it is strongly significant when the results of all agents are pooled and the resulting temperature coefficient is −5.4% (95% CI −4.5%, −6.2%) of the solubility at 37 °C.

Figure 3 shows our mean results on the same plot as group results from other studies; the proposed linear correlation fits adequately and the significant difference found with enflurane is of little consequence. When the temperature coefficients for halothane from the studies cited previously are expressed in terms of solubility at 37 °C (6.5%,[1] 5.7%,[2] 4.6%,[3] 4.8%[4]), the most recent measurements are seen to agree closely with ours. Eger and Eger's result of 5.8% for enflurane also agrees well, giving us confidence in our method.

When measuring the partial pressure of an anaesthetic in blood, the temperature coefficient is used to correct for differences between blood temperature at the time of sampling and the temperature of the analysis. The 95% confidence interval for such a measurement is 5–10% of its value,[5] so a little uncertainty in the value of the temperature coefficient is tolerable. We therefore advocate the simple rule that the Ostwald solubility coefficient of anaesthetics in blood increases (or decreases) by 5.4% of the coefficient at 37 °C for every degree decrease (or increase) in temperature within the clinical range.

Studies on the binding of [^{3}H]amethocaine to rat cerebrocortical membranes

T. KUDO, M. KUDO, K. HIROTA AND D. G. LAMBERT

Summary

We have examined the binding of the local anaesthetic agent [^{3}H]amethocaine to rat cerebrocortical membranes. All studies were performed in Tris buffer 50 mmol litre^{-1} at pH 7.4. Bound and free radioligand were separated by rapid vacuum filtration. [^{3}H]Amethocaine binding at room temperature was dose-dependent and saturable, with mean K_d and B_{max} values of 153 (SEM 18) nmol litre^{-1} and 9.4 (1.6) pmol/mg protein, respectively. [^{3}H]Amethocaine binding was displaced in a dose-dependent manner (pIC$_{50}$) by unlabelled amethocaine (6.89), procaine (5.20), lignocaine (3.46) and prilocaine (2.81). Ropivacaine and bupivacaine did not produce 50% displacement at the highest concentrations used (10^{-4} and 10^{-3} mol litre^{-1}, respectively). We examined the nature of the binding site further with a range of ion channel antagonists (nifedipine, verapamil, diltiazem, ω-conotoxin, tetrodotoxin, tetraethylammonium and 4-aminopyridine) and ion channel coupled receptor ligands (L-glutamate, MK801, GABA, glycine and nicotine). With the exception of tetraethylammonium (pIC$_{50}$ 3.07) and 4-aminopyridine (pIC$_{50}$ 3.68), all non-anaesthetic agents failed to displace [^{3}H]amethocaine. Collectively our data suggest that it is unlikely that there is a single target site for all local anaesthetic agents. (*Br. J. Anaesth.* 1997; **79**: 521–524).

Key words
Anaesthetics local, amethocaine. Model, rat. Ions, ion channels.

It is well known that local anaesthetics interact with membrane Na$^+$ channels to inhibit information flow in neurones.[1–3] However, there is now growing evidence for an additional site(s) of action, including voltage-sensitive Ca^{2+} channels (VSCC).[4–7] Indeed, we have reported previously that a range of local anaesthetic agents at clinically relevant concentrations interact with L-type VSCC channels in rat cerebrocortical membranes.[8 9] We demonstrated that procaine, prilocaine, lignocaine, amethocaine and bupivacaine displaced the binding of an L-channel radiolabel, [^{3}H]PN200-110, with a rank order potency that correlated with the lipid solubility of these agents.[9] In this study we report dose-dependent and saturable binding of [^{3}H]amethocaine to rat cerebrocortical membranes and examine the effects of a range of local anaesthetic agents and transmitters/channel blockers with this binding site.

Materials and methods

MEMBRANE PREPARATION

All studies were performed in rat cerebrocortical membranes resuspended in Tris HCl 50 mmol litre^{-1}, pH 7.4 (prepared as described previously) by homogenization and centrifugation.[9 10]

[^{3}H]AMETHOCAINE BINDING ASSAY

In order to determine the maximum binding capacity or total number of binding sites (B_{max}) and the equilibrium dissociation constant for [^{3}H]amethocaine (K_d), membranes (approximately 50 μg of membrane protein) were incubated in 150-μl volumes with increasing concentrations (approximately 3–600 nmol litre^{-1}) of [^{3}H]amethocaine (>95% pure, 43 Ci mmol^{-1}, Amersham International, UK). In addition, we attempted to determine the K_d kinetically by measuring the ratio of the dissociation rate constant (K_{-1}) to the association rate constant (K_{+1}). In these studies, membranes (approximately 750 μg) were incubated in 1-ml volumes with approximately 1 nmol litre^{-1} of [^{3}H]amethocaine to equilibrium (>15 min at room temperature and >2.5 h on ice). At 60 min (room temperature) or 3 h (ice), dissociation was initiated by the addition of unlabelled amethocaine 1 mmol litre^{-1}.

For displacement studies the assay volume was 1 ml and a fixed concentration of [^{3}H]amethocaine (approximately 1 nmol litre^{-1}) was used. Agents that displace [^{3}H]amethocaine are likely to interact at the same target site or to be coupled allosterically to the [^{3}H]amethocaine binding site. Increasing concentrations of unlabelled amethocaine, lignocaine, procaine, prilocaine, bupivacaine and R(+)/S(−)ropivacaine were added and the

concentration producing 50% displacement (IC_{50}) determined. In addition, displacement studies were performed with the following ion channel blockers/transmitters in order to examine the site(s) of interaction: nifedipine, verapamil, diltiazem (L-type VSCC blockers), ω-conotoxin GVIA (N-type VSCC blocker), tetrodotoxin (Na^+ channel blocker), tetraethylammonium (K^+ channel blocker), 4-aminopyridine (4-AP; K^+ channel blocker), L-glutamate, MK801 (NMDA receptor ion channel blocker), GABA, glycine and nicotine. In all experiments non-specific binding (NSB) was defined in the presence of excess (1 mmol $litre^{-1}$) unlabelled amethocaine. Saturation, kinetic and amethocaine isotope dilution studies were performed at either room temperature (approximately 23 °C) or on ice (approximately 0 °C to limit ligand dissociation). Bound and free radioligand were separated by rapid vacuum filtration.

DATA ANALYSIS

All data are presented as mean (SEM) (*n*). Saturation data were analysed according to Scatchard.[11] Observed association (K_{ob}) and dissociation (K_{-1}) rate constants were estimated from non-linear, one-phase exponential association and dissociation equations using Graphpad-Prizm. K_{ob} was corrected for K_{-1} and the concentration of [^{3}H]amethocaine to yield K_{+1}. K_d was then calculated using K_{-1}/K_{+1}. The concentration of displacing drug producing 50% displacement of specific binding (pIC_{50}) was estimated from individual curves by non-linear regression (Graphpad-Prizm). In some experiments 100% displacement was not achieved and data were analysed based on an assumed 100% displacement.

Results

Binding of [^{3}H]amethocaine was dose-dependent and saturable at room temperature (fig. 1A, B) and on ice (data not shown). Scatchard analysis of the specific binding data on ice and at room temperature yielded K_d and B_{max} values of 169 (20) nmol $litre^{-1}$, 11.0 (1.6) pmol/mg protein and 153 (18) nmol $litre^{-1}$, 9.4 (1.6) pmol/mg protein, respectively. At the radioligand K_d specific binding was in excess of 50%. Unlabelled amethocaine 1 mmol $litre^{-1}$ was added to membranes labelled for 60 min at room temperature (fig. 1C) and 3 h on ice (data not shown) in an attempt to initiate ligand dissociation.

Table 1 pIC_{50} values (mean (SEM)) for local anaesthetic displacement of [^{3}H]amethocaine binding at room temperature to rat cerebrocortical membranes. *Determined by isotope dilution

Local anaesthetic	*n*	pIC_{50}	IC_{50}

Nicotine	10^{-3}	6	29.1 (2.6)

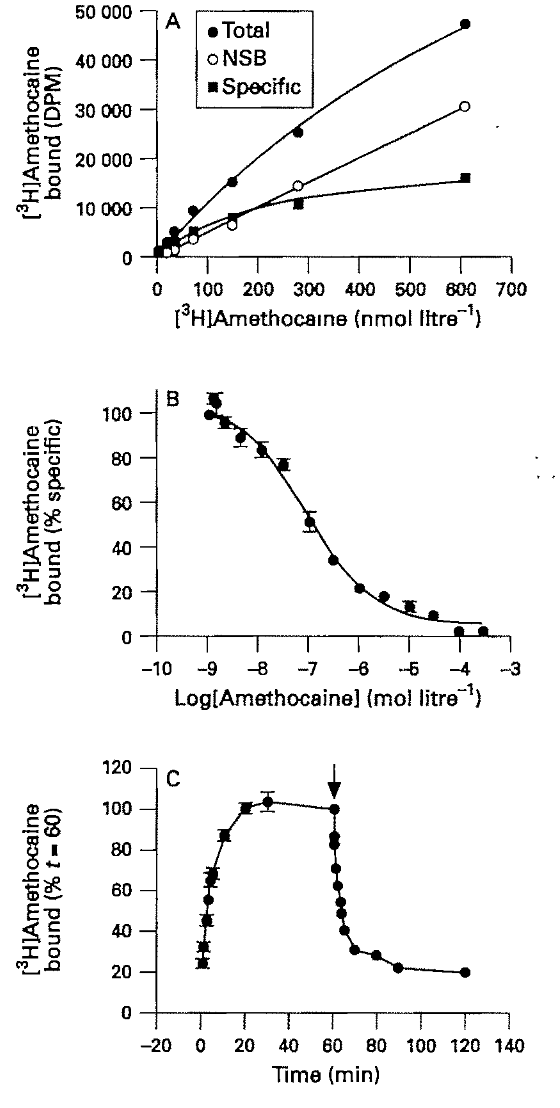

Figure 1 [^{3}H]Amethocaine binding (total, non-specific (NSB) and specific) to rat cerebrocortical membranes incubated at room temperature was dose-dependent and saturable (A) and displaced in a dose-dependent manner by unlabelled amethocaine (B). Association and dissociation time courses for [^{3}H]amethocaine (approximately 1 nmol $litre^{-1}$) binding are shown in (C). In (C), ligand dissociation was initiated by addition of excess unlabelled (1 mmol $litre^{-1}$, arrow) amethocaine and data are expressed relative to the t=60 time point normalized to 100%. Data are from a single representative experiment (from n=15) in (A), and mean (SEM) (n=11) in (B) and (n=6) in (C).

At room temperature, <20% of ligand had dissociated by 15 s and there was no appreciable dissociation on ice. Kinetic analysis yielded K_{ob} and K_{-1} values on ice and at room temperature of 0.023 min^{-1} and 0.001 min^{-1} (n=2) and 0.307 (0.026) min^{-1} and 0.299 (0.016) min^{-1} (n=6), respectively. As K_{ob} was so close numerically to K_{-1}, a dissociation constant value could not be calculated. In order to confirm the K_d value obtained in saturation studies, K_d was estimated in a series of isotope dilution studies where [^{3}H]amethocaine was displaced by unlabelled amethocaine (fig. 1B). pIC$_{50}$ (approximate K_d) values of 6.97 (0.05) (107 nmol litre^{-1}) and 6.89 (0.02) (129 nmol litre^{-1}) were obtained on ice and at room temperature, respectively.

A range of unlabelled local anaesthetics displaced [^{3}H]amethocaine binding in a dose-dependent manner, with pIC$_{50}$ values (as concentration of radiolabel was negligible compared with the K_d, IC$_{50}$ values are presented uncorrected for the competing mass of [^{3}H]amethocaine) shown in table 1. The rank order potency was amethocaine>procaine>lignocaine>prilocaine. Hill numbers for procaine, prilocaine and lignocaine were 0.65, 0.72 and 0.81, respectively, perhaps suggesting interaction with more than one site. However, these Hill numbers should be interpreted with caution because of the lack of complete displacement by these agents. Further discriminatory analyses were not performed. At bupivacaine 1 mmol litre^{-1}, R(+)ropivacaine 10^{-4} mol litre^{-1} and S(−)ropivacaine 10^{-4} mol litre^{-1}, 15.7 (1.7) %, 27.4 (1.5) % and 26.1 (1.0) % displacement was observed. There was no significant correlation between lipid solubility (measured as octanol:buffer partition coefficient[12]) and the pIC$_{50}$ for displacement of [^{3}H]amethocaine binding (r^2=0.47, P=0.31). Of the non-local anaesthetic agents tested, only 4-AP and tetraethylammonium produced greater than 50% displacement of specific binding with estimated pIC$_{50}$ values of 3.68 (0.02) (209 μmol litre^{-1}) and 3.07 (0.05) (851 μmol litre^{-1}), respectively (table 2).

Discussion

We have demonstrated dose-dependent and saturable binding of [^{3}H]amethocaine to rat cerebrocortical membranes. The binding was displaced by a range of unlabelled local anaesthetic agents but there was no correlation with lipid solubility, and bupivacaine and ropivacaine failed to produce 50% displacement at the maximum concentrations used. In addition, binding of [^{3}H]amethocaine was displaced by the K$^+$ channel blockers, 4-AP and tetraethylammonium.

The K_d values calculated by Scatchard analysis (153 nmol litre^{-1} at room temperature, 169 nmol litre^{-1} on ice) and by isotope dilution (129 nmol litre^{-1} at room temperature, 107 nmol litre^{-1} on ice) compare favourably with the values quoted by Grima and colleagues[13] and Reith, Kim and Lajtha[14] of approximately 170–180 nmol litre^{-1} in synaptosomes (an excitable preparation) analysed according to Scatchard.[11] B$_{max}$ values quoted in this study (approximately 13 pmol/mg protein) compare well with our data. In addition, Voight and Mannhold have reported binding of [^{3}H]lignocaine in a range of predominantly peripheral tissues concluding that the pharmacological significance of the binding site remains to be determined.[15] It should be noted that in these studies the emphasis was to examine binding to Na$^+$ channels rather than to use the radiolabelled local anaesthetic to examine "anaesthetic binding sites".

Binding of [^{3}H]amethocaine was displaced in a dose-dependent manner by amethocaine, procaine, lignocaine and prilocaine. There was no correlation between displacement of [^{3}H]amethocaine binding (pIC$_{50}$) and lipid solubility or anaesthetic potency. In addition, ropivacaine and bupivacaine produced only approximately 25% displacement at the highest doses used. The lack of an interaction with all local anaesthetic agents implies that the binding site for [^{3}H]amethocaine in rat cortical membranes does not represent a common target site for local anaesthesia. However, it is possible that if soluble, and available at higher concentrations, bupivacaine and ropivacaine may have been able to produce 50% displacement but the pIC$_{50}$ values would be very weak. In our study amino-ester local anaesthetics (amethocaine and procaine) displaced with highest affinity while amino-amide local anaesthetic agents (lignocaine, prilocaine, bupivacaine and ropivacaine) displaced with the weakest affinity.

L-channel (nifedipine, diltiazem and verapamil) and N-channel (ω-conotoxin) antagonists failed to displace [^{3}H]amethocaine from its binding site, implying a lack of interaction with L- and N-type voltage-sensitive Ca^{2+} channels. However, these studies report a lack of "direct" channel interaction and possibly the absence of an allosteric interaction between the displacer and [^{3}H]amethocaine binding sites. It is still conceivable that the displacing agent could interact at another binding site(s) not coupled to the [^{3}H]amethocaine binding site. Our previous study of the effects of local anaesthetic agents with [^{3}H]PN200-110 binding sites (L channels) showed a significant interaction but we did not examine if the interaction was allosteric.[9] However, Bolger and colleagues have shown such an allosteric interaction with [^{3}H]nitrendipine binding sites in rat brain and cardiac membranes.[5]

L-glutamate and MK801 (agents that interact with glutamate receptors), GABA, glycine and nicotine failed to displace [^{3}H]amethocaine binding. We were unable to displace [^{3}H]amethocaine binding with the Na$^+$ channel blocker, tetrodotoxin. This is in agreement with the work of Grima and colleagues[13] although they reported displacement with amiloride (and analogues), an agent that also binds to voltage-dependent Na$^+$ channels.[16 17] 4-AP and tetraethylammonium, agents that interact with K$^+$ channels, produced dose-dependent displacement of [^{3}H]amethocaine binding, which for 4-AP resulted in an IC$_{50}$ of approximately 209 μmol litre^{-1}. However, it is not possible to state that local anaesthetic agents interact with K$^+$ channels based on these data alone.

In summary, we have reported dose-dependent and saturable binding of [^{3}H]amethocaine to rat cerebrocortical membranes that was displaced in a dose-dependent manner by a range of unlabelled local anaesthetic agents. Amino-ester agents were more potent than amino-amide anaesthetics, perhaps implying that a single common binding site for all local anaesthetic agents is unlikely. There did not appear to be a direct interaction with known ligand binding sites on L- or N-type VSCC, GABA, glutamate, glycine or nicotinic receptors. Our data suggest a possible interaction with K^+ channels. However, at present, a non-specific binding site cannot be excluded.

Dissociation between the effect of nitrous oxide on spontaneous and reflexly evoked sympathetic activity in dogs

D. MA, C. WANG, C. K. PAC-SOO, M. K. CHAKRABARTI AND J. G. WHITWAM

Summary

We have examined the effect of nitrous oxide on spontaneous sympathetic activity and Aδ- and C-fibre mediated somatosympathetic reflexes in renal nerves, evoked by supramaximal electrical stimulation of radial nerves in anaesthetized, paralysed dogs undergoing mechanical ventilation. In six preparations, nitrous oxide was administered at end-tidal concentrations of 10%, 30%, 50% and 70%, each for 20 min. Spontaneous renal sympathetic activity increased significantly to 147.8% and 151.2% of control values with 50% and 70% nitrous oxide, respectively (*P*<0.05), but there were no significant changes in Aδ and C reflexes We conclude that the large increase in spontaneous sympathetic activity was dissociated from somatosympathetic reflexes which remained unchanged at these concentrations of nitrous oxide. (*Br. J. Anaesth.* 1997; **79**: 525–529).

Key words
Anaesthetics gases, nitrous oxide. Nerve, somatic. Reflexes, sympathetic. Sympathetic nerve system. Dog.

Previously, several studies have demonstrated that nitrous oxide increases sympathetic outflow in both humans and animals. Indirect evidence of sympathetic activation, which has been summarized by Eisele,[1] obtained from volunteers breathing 40–60% nitrous oxide, is that it increases arterial pressure and heart rate,[2] cardiac output, plasma catecholamine concentrations,[2 3] systemic vascular resistance,[2 4] and causes pupillary dilatation[2] and sweating.[5] Direct evidence for sympatho-excitation by nitrous oxide has been studied by recording activity in sympathetic nerves in humans[6] and cats.[7] Although the effect of nitrous oxide on somatosympathetic reflexes has been observed in the cat,[8] it was studied at a concentration of only 75%, and there were no data for spontaneous sympathetic activity. Other studies have also used a limited range of concentrations,[6 7] and no previous study has attempted to relate the increase in spontaneous sympathetic activity with a possible effect on somatosympathetic reflexes. In this study we examined the effect of increasing concentrations of nitrous oxide on both spontaneous sympathetic activity and Aδ and C somatosympathetic reflexes.

Materials and methods

The study was approved by the UK Home Office (license PPL 90/00852). Six beagles, weighing 13.5–18 kg, were studied. Anaesthesia was induced with methohexitone 10–15 mg kg^{-1} i.v. and maintained using 1% α-chloralose in an initial bolus dose of 30 mg kg^{-1} followed by an infusion of 15–20 mg kg^{-1} h^{-1} i.v. The trachea was intubated and the lungs ventilated with oxygen-enriched air (HV 2000, SLE, Croydon, UK). Neuromuscular block was maintained with bolus doses of suxamethonium 10 mg i.v. every 30 min. An 18-gauge cannula was inserted into a cephalic vein in the right foreleg for drug and fluid administration. The left femoral artery was cannulated for recording arterial pressure and blood sampling. A Swan-Ganz catheter (American Edwards Laboratories) was inserted via the left femoral vein for measurement of cardiac output, central venous pressure (CVP), pulmonary arterial pressure (PAP) and pulmonary capillary wedge pressure (PCWP). Cardiac output was measured by thermodilution with a cardiac output computer (Com-1, American Edwards Laboratories). Oesophageal temperature was measured with a thermistor (Yellow Spring Instruments, OH, USA) and maintained at 37–39 °C with a heater built into the operating table. Arterial blood-gas tensions and pH_a were determined using a blood-gas analyser (Radiometer ABL 3, Copenhagen, Denmark); values were kept within limits (pH_a 7.30–7.40, arterial carbon dioxide partial pressure (Pa_{CO_2}) 4.8–5.3 kPa and arterial oxygen tension (Pa_{O_2}) 22.7–28.0 kPa) by adjusting ventilation and occasional administration of sodium bicarbonate. For each preparation, pH_a and blood-gas tensions were maintained close to control values during all relevant recordings. There were no significant changes in each preparation with only small differences in Pa_{CO_2} and pH_a between preparations; Pa_{O_2} was maintained above the chemoreceptor threshold (table 1). Arterial and venous pressures were measured with strain gauge transducers (Statham, Oxnard, CA). Heart rate was

obtained from the arterial pulse wave. All haemodynamic signals were amplified, displayed on a monitor and stored on disk for later analysis (Maclab Software, AD Instruments Pty Ltd, Australia). Systemic (SVR) and pulmonary (PVR) vascular resistances were calculated using standard formulae (SVR=(MAP−CVP)×80÷CO, PVR=(PAP−PCWP)×80÷CO).

ELECTROPHYSIOLOGY

Surgical procedures

After setting up, the preparation was placed and maintained in the left lateral position. The lateral branch of the superficial branch of the radial nerve was exposed in the left foreleg, desheathed and cut distally, and mounted on silver–silver chloride electrodes in a pool of mineral oil for electrical stimulation. The renal sympathetic nerves were exposed retroperitoneally alongside the renal artery; a single fascicle was desheathed, cut distally near the kidney, immersed in a mineral oil pool and mounted on silver–silver chloride electrodes for recording sympathetic activity.

Electroneurogram and signal processing

Efferent activity in renal sympathetic nerves was processed through a pre-amplifier (Tektronix type 122) and displayed on a dual-beam oscilloscope (Tektronix type 565). Supramaximal electrical stimuli (frequency 0.33 Hz, intensity 30 V, duration 0.5 ms) were applied to the radial nerve by a stimulator (S88, Grass, Quincy, MA). Evoked somatosympathetic responses recorded in renal sympathetic nerves were averaged (16 responses), rectified and integrated using a neurolog system (NL 90, Welwyn Garden, UK). Both amplified and integrated signals were displayed on an oscilloscope and hard copy was recorded with a thermal system (Gould 1602, Essex, UK). For spontaneous sympathetic activity, the signal was subjected to full-wave rectification and then integrated with a time constant of 100 ms (Neurolog NL 90). The total electrical activity in the integrated signals of evoked sympathetic reflexes, and spontaneous sympathetic activity during 20-s periods was measured in arbitrary units. Data were based on the average of three measurements at each point in each preparation and subsequently expressed as a percentage of control values.

ADMINISTRATION OF NITROUS OXIDE

The preparation was allowed to stabilize for at least 1 h after completion of surgery, before control measurements were obtained. Nitrous oxide was then administered to each of six preparations at 10%, 30%, 50% and 70% (expired end-tidal concentration) for 20 min, while maintaining $P\text{E}'_{O_2}$ at approximately 30% and Pa_{O_2} relatively constant above the chemoreceptor threshold; Pa_{CO_2} and pH_a were maintained at control values and adjusted when necessary before each data set was recorded (table 1). Expired concentrations of nitrous oxide were measured by a Datex Capnomac II, which was calibrated before each experiment with standard gas (Quick Cal, Datex Division of Instrumentarium Corp., Helsinki, Finland). Equilibrium end-tidal concentrations were used to compare the effect of changes in the concentration of nitrous oxide on evoked reflexes and spontaneous sympathetic activity. After initial control readings, measurements were repeated to obtain subsequent values towards the end of each 20-min period of nitrous oxide administration, immediately before the 5-min period of stimulation of the radial nerve necessary to produce a complete data set. Measurements were also repeated 1 h after withdrawal of nitrous oxide.

STATISTICAL ANALYSIS

All data are expressed as mean (SD). Statistical analysis was performed by analysis of variance (ANOVA) followed, where this showed significant differences ($P<0.05$), by paired t tests. Differences were considered statistically significant when $P<0.05$.

Results

SYMPATHETIC ACTIVITY

Figure 1 shows typical recordings of spontaneous sympathetic activity and Aδ- and C-fibre mediated somatosympathetic reflexes, evoked by supramaximal electrical stimulation of the radial nerve.

Mean spontaneous sympathetic activity increased to 111.9% of control values (ns) at 30% nitrous oxide and subsequently increased significantly to 147.8% and 151.2% of control values at 50% and 70% end-tidal concentrations of nitrous oxide, respectively ($P<0.05$). It remained at 112.4% of control values 1 h after nitrous oxide withdrawal but this difference was not statistically significant (fig. 2A).

There were no significant changes in Aδ and C reflexes throughout the study (fig. 2B).

HAEMODYNAMIC DATA

There were no significant changes in heart rate (HR) or mean arterial pressure (MAP) in the absence of

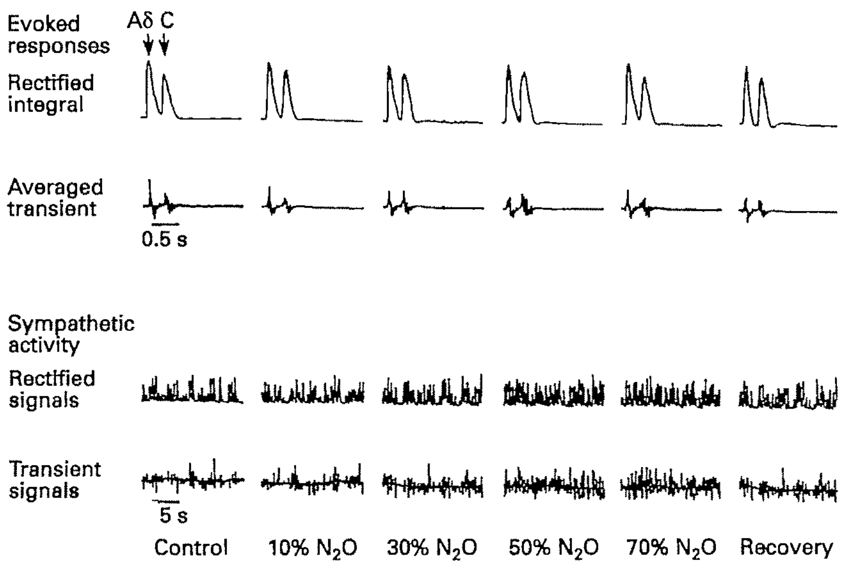

Figure 1 Data from one preparation showing the effect of nitrous oxide (N_2O) on spontaneous sympathetic activity, Aδ responses (early) and C responses (late). Top pair of traces—evoked responses: lower traces are averaged responses of Aδ and C reflexes (×16); upper traces are rectified and integrated signals. Bottom pair of traces—spontaneous sympathetic activity: lower traces are directly recorded activity, upper traces are rectified and integrated signals.

electrical stimulation of the radial nerve (fig. 3). There were small increases in HR and MAP during stimulation of the radial nerve but only some of the changes in MAP reached statistical significance ($P<0.05$).

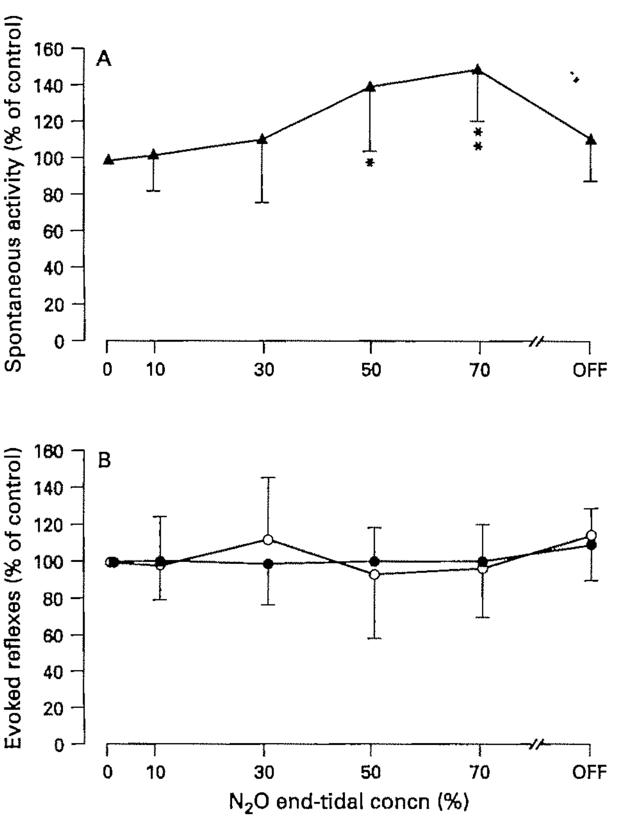

Figure 2 Effect of increasing concentration of nitrous oxide (N_2O) on (A) spontaneous renal sympathetic activity and (B) Aδ- and C-fibre mediated somatosympathetic responses evoked by supramaximal electrical stimulation of the radial nerves (mean (SD)) ($n=6$). ○=C-fibre responses; ●=Aδ-fibre responses. $^*P<0.05$; $^{**}P<0.01$ compared with control. There were no significant changes in Aδ and C reflexes throughout the study.

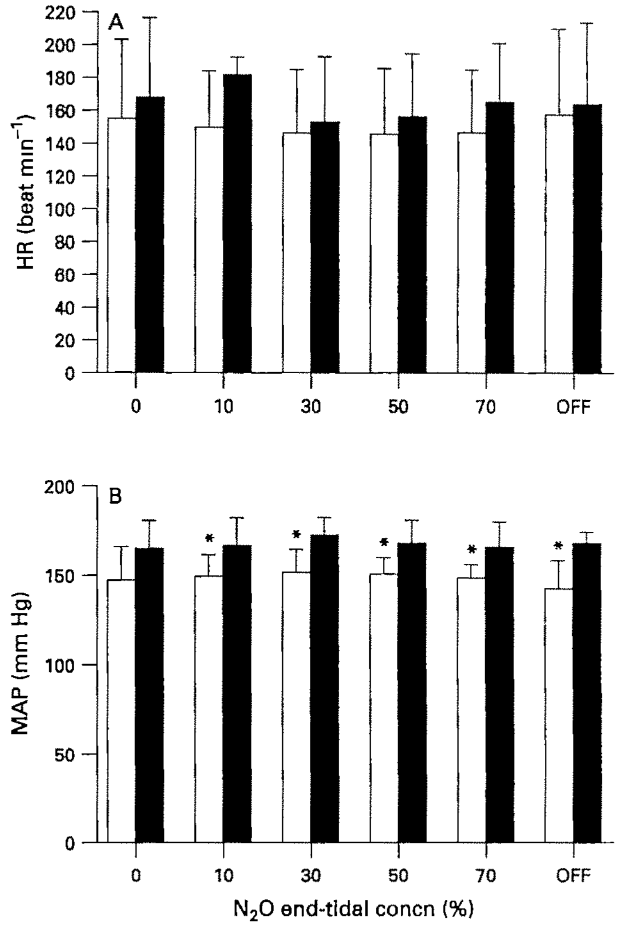

Figure 3 Changes in heart rate (HR) (A) and mean arterial pressure (MAP) (B) before (☐) and during (■) stimulation of the radial nerve at each concentration of nitrous oxide (N_2O) from 10% to 70% (mean (SD)) ($n=6$). $^*P<0.05$ for comparison between non-stimulated and stimulated values at each concentration of nitrous oxide. There were no significant differences compared with control.

Although mean cardiac output gradually increased to 1.85, 1.86, 1.87 and 1.91 litre min^{-1} from the control value of 1.71 litre min^{-1} after 10%, 30%, 50% and 70% nitrous oxide, respectively, this was not statistically significant, and returned to control after its withdrawal.

In this small number of animals there were no significant changes in SVR, PVR, CVP or PCWP.

Discussion

This is the first direct evidence of sympatho-excitation produced by nitrous oxide in a concentration-related manner, and also the first study combining data of its effect on spontaneous sympathetic activity and Aδ and C somatosympathetic reflexes. There were two main findings: nitrous oxide caused an increase in sympathetic activity which showed a sigmoidal relationship to increasing concentrations and which reached a maximum of approximately 50% at a concentration of 70% nitrous oxide; there was no significant change in Aδ- and C-fibre mediated somatosympathetic reflexes in response to administration.

Sympathetic outflow increases in response to hypotension and low venous pressure with low atrial pressures, because of baroreflexes, and an increase in Pa_{CO_2} or a low Pa_{O_2}. However, hypotension and low CVP did not occur during these experiments, Pa_{O_2} was maintained above the chemoreceptor threshold[9] and Pa_{CO_2} and pH_a near control values (table 1).Therefore, the increase in spontaneous sympathetic activity cannot be attributed to any of these physiological variables and was a reproducible response to nitrous oxide. We also considered the possibility that the periods of nerve stimulation could be a cumulative factor increasing spontaneous sympathetic activity. However, it was observed in pilot studies that spontaneous sympathetic activity always returned to control levels within approximately 5 min of ceasing stimulation, which confirmed many years' experience with a variety of experiments using similar preparations. Smith and colleagues reported that the addition of nitrous oxide to halothane–oxygen anaesthesia in humans produced vasoconstriction, increased oesophageal temperature and dilated the pupils.[2] Fukunaga and Epstein, using direct recordings of splanchnic nerve activity in cats anaesthetized with 0.9% halothane, found an increase of 13% in sympathetic activity after addition of 70% nitrous oxide to the inspired gas; they suggested that the increase in sympathetic activity produced by nitrous oxide was mediated centrally and caused by effects on neurones in suprapontine structures.[7] Ebert and Kampine reported that brief exposure to nitrous oxide in healthy volunteers caused an increase in efferent activity in sympathetic nerve fibres in the peroneal nerve innervating skeletal muscle.[6] Sellgren, Pontén and Wallin showed that in patients, nitrous oxide was associated with an increase in sympathetic activity in muscle nerves, which was obtunded by isoflurane in a concentration-dependent manner,[10] while Ebert reported that 40% nitrous oxide in human volunteers produced augmentation of baseline sympathetic nerve activity in nerves supplying skeletal muscles.[11] All of these observations are in keeping with the results of our study. The increase in sympathetic activity produced by nitrous oxide may be responsible in part for the relatively stable cardiovascular effects noted when it is administered together with other anaesthetic agents which depress the sympathetic nervous system. It represents a positive contribution to the critical debate for its continued use in some patients not only because of sympatho-excitation but also by allowing a reduction in the requirements of additional agents and drugs. However, its use in patients with cardiac disease or in those with endocrine disorders requires careful consideration.

The mechanism for central sympatho-excitation during nitrous oxide administration is unknown, and clearly an increase in excitatory neurotransmitters could provide an explanation. However, in decerebrate cats exposed to nitrous oxide, preganglionic splanchnic sympathetic activity is decreased rather than increased,[7] and hence the effect of nitrous oxide could be a result of depression of central inhibitory areas. It is interesting that in the last century nitrous oxide was originally regarded as an stimulant of the central nervous system, and only later were its analgesic properties appreciated.[12]

Nociceptive stimulation of afferent somatic sensory nerves causes changes in systemic arterial pressure and heart rate, which are mediated by the autonomic nervous system.[13] Directly recorded sympathetic responses to single supramaximal electrical stimuli applied to a somatic nerve show two bursts of activity, termed somatosympathetic reflexes, and are mediated by afferent Aδ and C fibres.[14] This study demonstrated clearly that nitrous oxide did not depress somatosympathetic reflexes at the concentrations used. Although it has been suggested that endogenous opioids are involved in its analgesic effects,[15] not all studies support this view.[16] It was suggested that nitrous oxide has little effect on the firing rate of dorsal horn neurones,[17] and Komatsu and colleagues[18] reported that the analgesic action of nitrous oxide can be attributed to activation of a descending supraspinal pain inhibition system. The MAC for nitrous oxide in the dog is equivalent to 188%,[19] and hence it would not be expected to suppress somatosympathetic reflexes except under hyperbaric conditions. However, Ogawa and colleagues[8] reported that a "late" reflex potential evoked by electrical stimulation of the femoral nerve was depressed by inhalation of 75% nitrous oxide in oxygen in cats, which has not been confirmed in our study in the dog.

It could be postulated that sympatho-excitation by nitrous oxide would enhance nociceptive somatosympathetic reflexes. Alternatively, when the sympathetic nervous system is already highly active, nociceptive stimulation may fail to induce further spatial or temporal summation and hence excitation within a rhythmically repetitively depolarized pool of sympathetic neurones, and because of such occlusion, the evoked responses could be depressed below control values. As neither occurs, the term dissociation was applied to the relative effects of nitrous oxide on spontaneous and evoked sympathetic activity.

In summary, by causing increases of up to 50% in spontaneous sympathetic activity, nitrous oxide provides the greatest central stimulus to the sympathetic system of all inhalation agents so far described and its effect is concentration dependent. In contrast, at 70% concentration it has no effect on Aδ- and C-fibre mediated somatosympathetic reflexes, in spite of a high level of spontaneous sympathetic excitation, indicating dissociation of its effects.

REVIEW ARTICLE

Anaesthesia for the surgery of emphysema

I. D. CONACHER

Thoracic anaesthesia is now established in a third age. The first age related to surgery for infective conditions, predominantly tuberculosis, the second was defined by surgery for bronchogenic cancer and the third is surgery for respiratory failure. The anaesthetic imperatives of this latest age are epitomized by emphysema, with some variants treated with lung transplantation and, recently, surgery for the oxymoron, lung volume reduction.

Small areas of emphysematous changes are common in the general population, occasionally resulting in pneumothoraces; a significant number of these patients require surgical intervention. The presence of large cystic areas or bullae, and bilateral, widespread diffuse areas of enlarged air spaces distal to terminal bronchioles[32] are much rarer and their management fraught with risk. Until the advent of lung volume reduction surgery, the anaesthetic literature was sparse, with mostly case reports and series involving small numbers. Personal experience of managing cases with moderate to severe respiratory failure, as a result of end-stage emphysematous disease, serves as an illustrative framework (table 1) and has much to teach about the dangers, how anaesthesia may contribute to morbidity and mortality, and where risks can be reduced.

An early specimen of emphysema, purportedly the lung of Dr Samuel Johnson, is illustrated in Mathew Baillie's *The Morbid Anatomy of Some of the Most Important Parts of the Human Body* (London, Bulmer, 1812).[47] Laennec[42] described the clinical condition of dyspnoea, cyanosis, dry cough, over-inflated chest, cardiac hypertrophy and quiet respiratory sounds on auscultation. He recognized the continuum from the small areas of enlarged air cells, illustrated in his book, to the giant cyst or bulla. He foresaw pathognomonic features now so often seen on chest x-rays and CT scans,[74] noting that: "When this disease occupies only one side, or exists much more in one lung than the other, this side is evidently enlarged, and the intercostal spaces wider...........and instead of its natural compressed shape it (the chest) exhibits an almost rounded or globular outline".[42]

John Snow[22] had an interest in the condition and recorded its occurrence in some of his patients. A particular danger of anaesthesia was noted 100 yr later: "A dangerous state of affairs may exist in the rare case of a cyst, usually large, of the lung, communicating with a bronchus. The communication is often valvular so that on inflation the cyst is distended without reduction in size during deflation. Compression of the surrounding lung occurs. If the condition is unsuspected by the anaesthetist, the more energetic his attempts at resuscitation by inflation, the more the lungs are collapsed by increasing distension of the cyst. Rapid asphyxia and death of the patient results unless the chest is quickly opened and the lungs allowed to expand".[51]

This classic description of the "*breath stacking*" and "*pulmonary tamponade*" effect of positive pressure ventilation and of over enthusiastic resuscitation is as true today as it was 40 yr ago. However, opening the chest rapidly would not be regarded as a modern first aid measure, although if occurring on induction of anaesthesia such a manoeuvre may be considered.[5] Deliberate decompression of bullae with intercostal drains remains an option, particularly to pre-empt the development of tension pneumothorax during anaesthesia.[20]

Surgery of bullae and diffuse emphysema

There are occasional reports of operations being conducted for bullae before the Second World War[31] but it was only when manifestations were gross that surgery was an option. Belcher described 90 patients with large bullae on whom he had operated since the early 1950s.[2] There was a 12% operative mortality rate and at follow-up, in some cases 10 yr after surgery, 35% had died but more than 50% had demonstrably improved. Hugh-Jones, Ritchie and Dollery[33] reported a 10% operative mortality rate. From then on, a variety of surgical options for obliteration of bullae were described; some, based on physiological misconceptions, were bizarre. Segmental resection,[29] lobectomy,[87] plication[3] and local excision[85] were suggested as suitable techniques for selected cases with well localized lesions of various sizes. Tracheostomy,

autonomic denervation, pneumoperitoneum, costochondrectomy, thoracoplasty, tracheal stenting and intracavity suction and drainage[44] have had their advocates.[1 19 57] In the latter, a forerunner of minimal access surgical techniques, the reported operative mortality rate was 6.5%. Recently, laser and videoscopic technology have been used to ablate small bullae.[84]

In 1959, Brantigan, Mueller and Kress[6] reported on the surgical management of diffuse emphysema but a high mortality (18%)[68] dissuaded many from surgical options until the advent of transplantation. For generalized conditions, such as α_1-antitrypsin deficiency, single lung transplantation was used, initially with little success,[83] but with advances in transplantation, single,[14 37] double[66] and heart–lung transplants[5] are all now practised with satisfactory results. From the experience has come the realization that some of the benefit is mechanical rather than physiological. The smaller functional residual capacity (FRC) of the transplant enables chest wall and diaphragm dynamics to improve so that function is more efficient. This is the basis of a resurgence in interest in early surgical options for diffuse bullous emphysema, such as lung volume reduction, which uses techniques and lessons from transplantation, new technologies (lasers and thoracoscopes), and modern suturing, stapling and buttressing materials.[16 24 75] The original premise was that reducing lung volume would improve elastic recoil and exercise circumferential traction on small airways, reducing the propensity for air trapping.[6] The main reason for success is improved airflow[17] and more efficient chest wall and diaphragm mechanics, as suggested originally.[6] But other factors that may be relevant are recruitment of alveoli compressed by bullae and improvement in ventilation–perfusion matching resulting from reduced pulmonary vascular resistance, improved right ventricular performance and greater venous return consequent on reduction of mean intrathoracic pressure.[71 88] There is evidence that improvement is rapid, within hours of surgery.[80 81]

Hard lessons of experience

Two cases (table 1) serve as illustrations of how the anaesthetic and surgical process can be particularly hazardous and set off a train of events that ultimately may be fatal.

CASE NO. 1

A 47-yr-old female with bilateral emphysema secondary to α_1-antitrypsin deficiency was undergoing a right single lung transplant. After induction of anaesthesia, a double-lumen tube was inserted. The procedure was uneventful until the start of one-lung ventilation. A bulla, or some bullae, became over inflated. Hyperinflation occurred impeding venous return. Barotrauma progressing to bilateral pneumothorax, pneumopericardium and pneumoperitoneum followed in rapid succession and despite commencement of cardiopulmonary bypass, venous return remained poor, hypoxaemia increased and death occurred.[13]

CASE NO. 2

A 61-yr-old male, house bound, with large bilateral apical bullae and a march tolerance of 10 yards, was anaesthetized for plication of a left apical bulla using conventional (for the time, 1981) one-lung anaesthesia. "*The bulla was twisted and obliterated and then multiple ligatures were placed round the resulting cord of tissue. The same was done to one smaller bulla in the upper lobe........The lung was then re-inflated and it was noted that a large bulla appeared spontaneously in the lower lobe.*" (operation note). The trachea was extubated and the patient returned to recovery. Two hours later he was comatose with a pH of 7.07, Pa_{CO_2} of 12.0 kPa and Pa_{O_2} of 10.6 kPa while receiving 40% oxygen. He was resuscitated and his trachea re-intubated for a short time before being extubated with an infusion of doxapram and low-dose ketamine for analgesia. His condition deteriorated overnight and intermittent positive pressure ventilation was commenced. A large air leak occurred from the left lung which in due course collapsed. A bulla in the right lung began to expand and mediastinal shift to the left occurred. A double-lumen tracheal tube was inserted. Asynchronous independent lung ventilation was started with resolution of some of the problems of the right lung but an increase in the left-sided air leak. Progressive circulatory and organ deterioration occurred culminating in the patient's death.

Case No. 1 illustrates the effects of induction of anaesthesia in instituting unnatural pressures and forces that can lead to haemodynamic collapse, volutrauma and barotrauma. Air from alveolar rupture tracked in a malignant manner, in the same way that was demonstrated more than 50 yr ago[46] and more recently reported in patients undergoing artificial ventilation and with adult respiratory distress syndrome.[86] Case No. 2 also illustrates the problems of applying supranormal airway pressures to damaged lung weakened by surgery, the longer term problems of providing adequate analgesia for the self-ventilating patient and the consequences of prolonged air leak. The latter is the main cause of postoperative morbidity[57] and predisposes to infection, marasmus and multiple organ failure.

Anaesthetic assessment

The anaesthetist should be aware that postoperative progress is an ordeal, particularly if air leaks develop. For patients to maintain self-ventilation for as long as possible implies that effort must be sustained at considerable expense to energy reserves. Adequate nutritional status, with implementation of enteral and parenteral supplementation if necessary, to reduce the cachectic state of many sufferers of emphysema is seen as an important part of the rehabilitation programmes to which many institutions subject potential lung transplant recipients and those undergoing lung volume reduction.[7]

Non-invasive assessment of right ventricular function[18] is important as pulmonary vascular resistance almost certainly increases during anaesthesia, application of positive pressure ventilation and commencement of one-lung ventilation.[59 60]

The quality of lung that is to function for gas exchange is paramount. Bullae, even "giant" in nature, may constitute little hazard as the affected lung can be isolated and routine one-lung ventilation conducted (case No. 3, fig. 1) on the contralateral one. But, as it is now common, particularly for diffuse disease, to operate on both lungs[4 15 35] (case No. 4) it is necessary to examine both lung fields from the perspective of having to alternate the lung to be used for gas exchange, ventilation and anaesthesia during surgery. One concomitant risk factor is obstructive airways disease.[77] The presence of widely dispersed non-homogeneous and diffuse pathology is particularly hazardous as each cystic area functions differently, has different pressure–volume and time constants, and different resistance to positive pressure generated by externally applied positive pressure or auto-generated by gas trapping.[26 27 40 64 73 78] Most of the relevant information for predicting the patient at high risk can be obtained from the chest x-ray, CT scan of the chest and ventilation–perfusion scans.[49] These investigations aid decisions to the most suitable method of achieving one-lung ventilation and whether or not selective bronchial blocking is likely to be of value. Assessing the state of the non-bullous lung fields is regarded as important to define the population most likely to benefit from radical surgery; for this, regional pulmonary function tests, such as dynamic ventilation volume using ^{133}Xe washout studies,[56] are recommended .

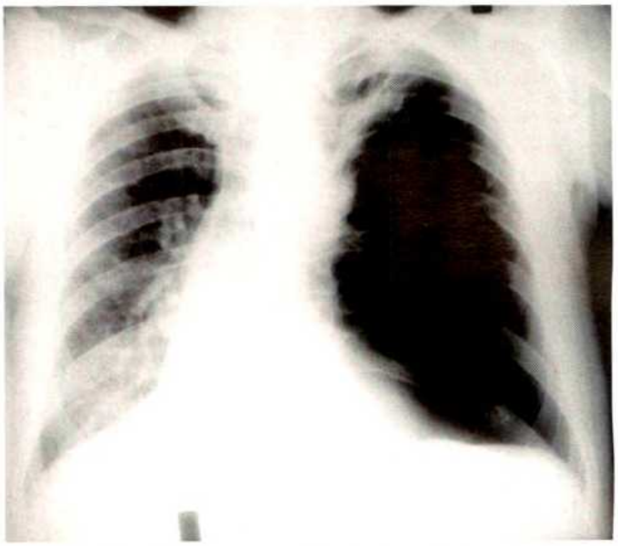

Figure 1 PA chest, case No 3. Left lower lobe bulla. Left lung isolated with a double-lumen tube. Bullectomy enabled re-expansion of compressed left upper lobe.

From the anaesthetic perspective, classification of bullae, traditionally[17] or according to surgical criteria,[84] is of little value as all types and sizes are prone to gas trapping phenomena. There is more value in a concept of clinically pathophysiological sub-groupings such as those friable enough to rupture and precipitate a tension pneumothorax before the chest is open, and those in which the feeding bronchus is dysfunctional and acts as a valve which precipitates hyperinflation after opening. The latter has subsets (a PEEP-dangerous subgroup and a PEEP-therapeutic subgroup) where an artificial expiratory resistance (PEEP$_e$) prevents the valvular mechanism becoming operational. There are few investigative or clinical indicators to these pathophysiological subsets, except the experience gained from trial and error with various ventilation techniques. There is no substitute for an expectant policy of gas trapping phenomena developing.

Anticipated predictors of poor outcome from surgery, such as those patients presenting with hypoxaemia and carbon dioxide retention (case No. 5) and those who fail to complete rehabilitation programmes, have in practice proved unreliable.[1] Measurement of intrinsic positive end-expiratory pressure (PEEP$_i$) is thought to be a predictor of outcome of lung volume reduction.[80] This index of air trapping is a potentially valuable measurement for the anaesthetist in the preoperative assessment of patients, indicating those most likely to suffer if further increases in intrathoracic pressure occur as a result of the anaesthetic process and aiding in decisions of the appropriateness and most therapeutic level of extrinsic PEEP ($PEEP_e$).[76]

Pre-induction of anaesthesia

There are no hard and fast rules to premedication.[7] Personal preference remains morphine and atropine premedication, as the antisialogogue element makes insertion of bronchoscopes and tracheal tubes less messy. Steroids and other bronchodilators have commonly been used; supplementation may be regarded as necessary at this phase.[7]

Patients should be prepared in the anaesthetic room as for a major case, with good venous access, invasive monitoring of arterial pressure from radial artery cannulation and central venous access. It should be borne in mind that the apices of the lung are vulnerable to needle punctures close to the traditional sites of large vein access and for this reason central venous access is safer from the antecubital fossae rather than neck or subclavicular approaches. With the various forms of lung transplantation, the requirement for cardiopulmonary bypass[18] dictates the level of monitoring but there should be a cautious and conservative attitude to the use of pulmonary flotation catheters, and indications for use are in those with concomitant left ventricular dysfunction[7 79] or in whom pulmonary hypertension is regarded as a potential problem.[5]

Pain relief must be optimal as soon as possible as it enables early tracheal extubation and rapid return to self-ventilation, regarded as crucial to the recovery of patients undergoing lung volume reduction. Those with pioneering experience regard it as so vital that extradural catheters are sited under fluoroscopic control to guarantee correct placement.[79] Personal preference is to site the extradural catheter in the seated conscious patient before induction of anaesthesia (case No. 6). High sites (T3–4) are advocated,[79] and with the patient sitting upright, needle insertion is at a comfortable height for the standing operator. At this level, in this position, the spinous processes are almost horizontal, making a midline approach to the extradural space easier. Other groups have found satisfactory analgesia from lumbar-placed catheters[34] after surgery.[5]

Most UK units (personal survey) use opioid and low-dose bupivacaine combinations, often with a patient-controlled mode to maintain analgesia during recovery. But it is a measure of how crucial is the extradural to the success of lung volume reduction surgery that some units recommend omitting the opioid component of extradural infusions because of the risk of nausea and vomiting.[79]

Induction of anaesthesia

In 1953, Mushin and Rendell-Baker,[51] reporting on the early experience of anaesthetizing patients with lung cysts, stated: "In these cases the need for inflation of the lungs should be carefully avoided until the chest is opened; relaxants and respiratory depressants are therefore contraindicated during induction of anaesthesia".

Elements of this statement remain true, based as it is on a premise that the safest levels of intrathoracic pressure are those during spontaneous, and unassisted, respiration and close to a negative mean. This concept underpins the general philosophy that patients who have undergone surgery for emphysematous conditions are safest breathing spontaneously as rapidly as possible after the procedure and the trachea should be extubated as early as possible. Neuromuscular blocking agents and respiratory depressant drugs are no longer regarded as contraindicated[7] but in view of the requirement for rapid antagonism, they should be pharmacologically specific and short acting. These enable optimum conditions for intubation with double-lumen tubes and suppress spontaneous respiratory activity, coughing and diaphragmatic activity which interfere with surgery. Atracurium, vecuronium, fentanyl and alfentanil are the current agents of choice, preceded by an induction dose of propofol which, with modern infusor systems, can be continued for maintenance of anaesthesia.

Hasenbos and Gielen[28] recommended a spontaneously breathing induction technique and double-lumen tracheal intubation under sedation and local anaesthetic for cases of giant bullae (case No. 7, fig. 2) and Myles and Moloney[53] used the technique to induce anaesthesia in a patient with a large air leak from a bulla. Further increases in the severity of disease of those undergoing operation, however, imply that even a coughing fit, for instance from maladroit administration of local anaesthesia to the larynx and trachea,[7] may precipitate the development of dynamic hyperinflation. Evidence is anecdotal, but the availability of sevoflurane will impact on some traditional reservations against gaseous induction in patients with sensitive and reactive airways. Conditions for safe intubation and positioning of double-lumen tubes can be achieved by induction of anaesthesia with etomidate or

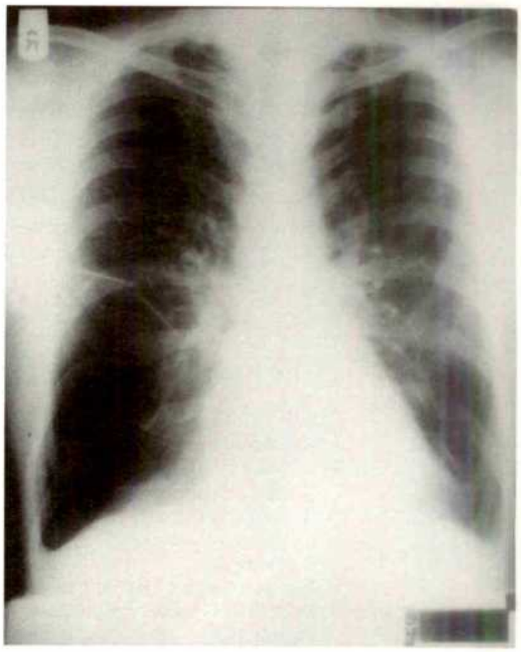

Figure 2 PA chest, case No 7. Right lower lobe bulla. Generalized emphysematous changes in both lung fields. High risk of gas trapping. Gas induction of anaesthesia.

propofol, short-acting opioids and non-depolarizing neuromuscular blocking agents, but it is essential that manual ventilation is commenced cautiously, with small tidal volumes, low inspiratory pressures and deliberate prolonged expiratory phases to atmosphere.[5 10] With such manoeuvres, hypoxaemia and hypotension have been avoided during induction of anaesthesia, and although carbon dioxide retention occurs, this is only to levels regarded as permissive.[5 65] The combined use of general anaesthetic and laryngotracheal local anaesthesia for intubation has been advocated and would seem worth considering, particularly for those with co-existent cardiac disease, to suppress the pressor effects of intubation, or in those patients in which isolation of a bulla from the ventilation system is a prerequisite.[58]

Control of the airway

A form of airway management that separates the lungs is mandatory. This is achieved most easily with a double-lumen tracheal tube but the Univent tube[38] has proved useful.[69] Double-lumen tubes add flexibility; lungs can be collapsed and expanded at will for surgical convenience; in the event of gas exchange problems, recruitment of the other lung is facilitated; and each lung can be ventilated and supported independently. For isolated left-sided lesions, an endobronchial blocker or a right-sided double-lumen tube can be inserted. For bilateral procedures, which encompass most lung volume reduction and sequential single lung transplantations, left-sided tubes should be used as the long main bronchus ensures more reliable lung separation and mitigates for bronchus leaks that impede surgery.

Maintenance of anaesthesia

Of the i.v. agents, propofol is the mostly recently advocated[10 39] supplanting agents such as gamma OH,[28] Althesin[58] and ketamine,[45] which were considered previously to have properties appropriate to the management of these physiologically unstable patients (in a climate where volatile agents were regarded as contraindicated because of effects on hypoxic pulmonary vasoconstriction).

There is no place for nitrous oxide; not only does it transfer into the air filled spaces[21 50] increasing intra-alveolar pressure with consequent effects on pulmonary capillary blood flow, but it also causes an increase in pulmonary vascular resistance.[70] However, volatile agents do have a place. I find them particularly useful when the chest is closed and the operation is ending. Neuromuscular block is antagonized as soon as the chest wall is sealed and the patient allowed to breathe spontaneously with oxygen and either enflurane or isoflurane. If ventilation is judged adequate, based on tidal ventilation, rate and effort, inspired oxygen is reduced gradually by introduction of an increasing concentration of air. In this way the potential for early extubation can be judged. Oxygenation status and haemodynamic variables remain the touchstones when the lungs are not visible. Some carbon dioxide retention causes no harm, providing oxygenation is maintained at safe levels.[5 10 65 79 82]

Routine, trusted indicators for fluid management, such as central venous pressure, are likely to be unreliable because of the gas trapping and pulmonary tamponade effect. Damage to the alveolar capillary membrane is likely in lung volume reduction surgery as there is much handling of the lungs. Fluid replacement is best controlled tightly within normal maintenance levels, as for lung transplantation, with predictable causes of hypotension, such as institution of positive pressure ventilation or the effect of local anaesthetic sympathetic blockade, treated cautiously with vasoconstrictors, inotropes and small infusions of colloid.[5 72]

Positive pressure ventilation

A misconception is that any one method of positive pressure ventilation is superior. Such are the pathophysiological variants that no technique is free of a proclivity to produce haemodynamic or barotraumatic complications.[26] Apart from reports of the use of self-ventilation techniques in whole or in part of a surgical procedure, all other commonly used systems have been used with success (table 2) or, it should be remembered, with failure. Essentially, it is not the technique but how and when it is applied, as any technique may be beneficial to the individual or

Table 2 Reported ventilation mode of patients with emphysema undergoing surgery

No. of cases	Type of surgery	Type of ventilation	Reference
1	Lumbar discectomy	Self-ventilation	[8]
1	Bullectomy	Self-ventilation	[28]
1	Coronary bypass graft	High frequency jet ventilation	[58]
1	Bilateral bullectomy	IPPV	[4]

Table 3 Stratagems for maintaining reduced mean and peak intrathoracic pressure

Use air:oxygen mix
Reduced tidal volume
  (7–8 ml kg^{-1} [79])
  Accept hypercapnia
Limit ventilator inspiration pressure (<20 cm H_2O)
Jet techniques—reduce injector size
Increase expiration phase
  I:E ratio (1:5[79])
  Prolonged interval[11]
Avoid PEEP
Revert to self ventilation asap

Any changes to patterns best conducted under direct vision of lungs, and via a period of manual ventilation

phase of the surgical procedure.[10, 79] The basic rule is to avoid application of excessive pressure at any point during a respiratory cycle; pressure is relative in these situations and an excess, by definition, differs from point to point throughout pathological lungs. Therefore, the safest starting point is to use manual inflation applied cautiously and proceed to a mechanical method with a low frequency, low inspiratory pressures (<20 cm H_2O) and expiration patterns that are without resistance (no PEEP)[7, 41, 79] and prolonged.[10] Various stratagems can be used to maintain the ventilation pattern within the confines that reduce the potential to gas trapping and dynamic hyperinflation (table 3). Jet techniques, if not used cautiously, can produce or exacerbate barotrauma,[10] and high frequency ventilation techniques are potentially dangerous because of the likelihood that high, occult PEEP is generated.[23]

With an open chest, one if not both lungs can be observed directly and the effects of ventilation assessed. It is vital that any changes in ventilation of the operated lung should be conducted under direct vision, manually, and with caution so that any pressure applied does not exacerbate damage caused by the surgical technique or predisposed by the pathology. The key therefore is flexibility and versatility, and several ventilation modes may be indicated during a case. Thus, in a recent case in a patient undergoing lung reduction via a sternotomy (case No. 6), on occasion, conventional positive pressure was applied using a pressure-limited ventilator or manual inflation applied via a Mapleson D system, and apnoeic oxygenation, in addition to self-ventilation depending on the stages of surgery. On occasion some of these systems were applied by deliberately deflating the bronchial cuff on the double-lumen tube to limit the pressure of ventilation to the other lung by allowing a large leak.[11]

Detecting dynamic hyperinflation

An understanding of dynamic hyperinflation is the result of experience of managing asthma in which it is recognized that dysfunctional airways and peribronchial cuffing create conditions for the development of an intrinsic expiratory pressure (auto PEEP or PEEP(i)), the consequences of which are air trapping.[40, 62] Preventing compounding of these patho-physiological elements[26, 73] by the processes of anaesthesia is dependent on the use of ventilatory patterns similar to those described previously.[67] Deliberate hypoventilation with permissive hypercapnia may be preventive and the treatment of choice in the established state. It is often not difficult to meet oxygen requirements as the large functional residual capacity associated with late-stage emphysema implies that frequent tidal delivery is not necessary.

Such techniques are not failsafe and it is necessary to recognize the early signs in the clinical setting[12, 54, 63] that warn of potential fatalities[43, 52, 55] (table 4). Improvement in any of the signs on disconnection of the ventilator is pathognomic[12] of a tension pneumothorax or of dynamic hyperinflation having a critical effect on cardiac function.[26] This simple manoeuvre may be life-saving until the tension is relieved with intercostal drainage or an appropriate ventilation mode established.

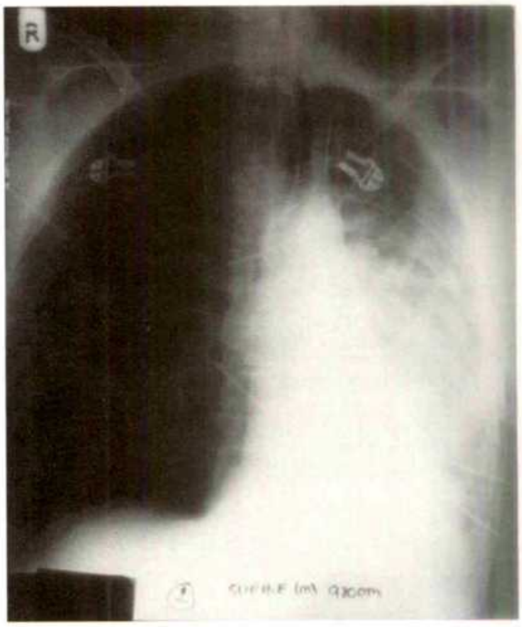

Figure 3 AP chest, case No. 8. The left lung is a transplant, compressed by the remnant native right lung.

Table 4 Detection of tension pneumothorax or dynamic hyperinflation in a clinical setting

Sign	Comment	Reference
Increased JVP	Difficult to see in patient undergoing surgery	[43]
Respiratory monitor waveform	Microprocessor controlled ventilators	[25, 30, 67]
Arterial trace waveform	Invasive arterial monitoring	[63]
Pulse oximetry	Paradoxical effect on arterial pressure and oxygenation	[11, 43]
Effect of disconnecting the ventilator	May be life-saving	

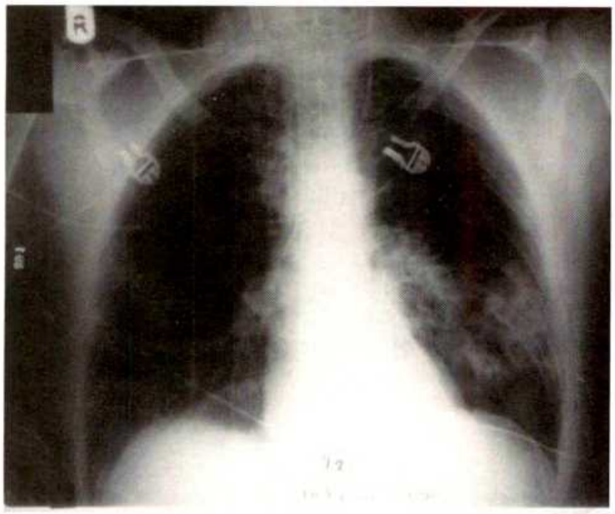

Figure 4 As in figure 3. A double-lumen tube has been placed in the right main bronchus. Independent lung ventilation has been started and the mediastinum has shifted centrally enabling the transplant to function.

Intensive care

It is possible to extubate the trachea of a patient who has undergone single lung transplantation at the end of surgery (case No. 8), and it is the norm to do so shortly after lung volume reduction surgery. However, this council of perfection cannot always be met. Single lung transplants characteristically[5 7 37] develop air trapping in the remnant natural lung which causes mediastinal shift and compromises the transplant. In the main, return to self-ventilation facilitates natural adjustments that sustain gas exchange but a few require double-lumen tube intubation and even a period of independent differential lung ventilation before this is possible (case No. 9, figs 3 and 4). For those who have already undergone extubation but are unable to maintain satisfactory blood-gas status, the use of vigorous physiotherapy, minitracheostomy and non-invasive methods of respiratory support should precede elective ventilation, which ultimately is a last resort and is associated with a poor prognosis. The use of Heimlich valves in those with small, but persistent air leaks can enable early discharge from high dependency units to the wards or even home.

Lessons for the non-specialist

As patients with a degree of emphysema are relatively common in the hospital population it is important to recognize the early signs of tension pneumothorax and dynamic hyperinflation. Knowledge of the negative effects on cardiac inotropism of air trapping exacerbated by positive pressure ventilation have been known for a long time.[32] But in the recent literature a few reports have suggested that the consequent dynamic hyperinflation is not as widely recognized as it should be by those involved in administering anaesthesia and resuscitation.[48 52] Signs may masquerade as primary right heart dysfunction or be interpreted as a pulmonary embolus of air, blood or tumour as the pulmonary tamponade acts in a similar way to a tourniquet on the heart.

Major, non-thoracic surgery is possible in those significantly compromised by bullae or emphysema.[8 20 36 58 61] Careful attention to detail, the use, whenever possible, of spontaneous ventilation and local anaesthetic techniques, and extradural analgesia during and after operation are key elements to success. The pursuit of normocapnia is a prerogative that can be sacrificed to a moderate degree ($Pa_{CO_2} \leqslant 12$ kPa).[5 9 10 53 65 82] Cannulation of a bulla, either accidental or therapeutic[44] to pre-empt the development of a tension pneumothorax,[20] may lead to the development of an air leak, requiring specialist surgical management and should not be undertaken lightly.

The efficacy of removal of functioning lung tissue in lung volume reduction surgery in improving patients in respiratory failure is a paradox that poses fundamental questions about accepted limits on lung resection and operative tolerability.[80] It is common for these patients to have pulmonary function less than 25% of predicted values. Previous constraints on surgery on grounds of fitness and arbitrary levels of respiratory dysfunction, such as carbon dioxide retention, minimal levels of forced expiratory volumes or maximum breathing capacities that equate with realistic effort required to maintain normocapnia,[11] are no longer tenable without qualification. The important distinction at a clinical level is between surgery that rapidly results in improvement in baseline (before surgery) lung function and improved chest wall dynamics, and that in which further deterioration (from baseline) is inevitable. This separates surgery for respiratory failure (lung transplantation and lung volume reduction surgery) from that for pulmonary resection for bronchogenic tumours and respiratory failure patients undergoing emergency surgery for lesions outside the thoracic cavity. In the latter there is a lag period as a result of a decrease in lung, chest wall and diaphragm compliance, attributable to the multifarious traumas of surgery, before improvement in pulmonary function. In the former, extubation can usually be performed early, while the latter probably requires positive pressure ventilation support after operation for a period until lung function returns to baseline.

Imperatives of the third age of thoracic anaesthesia

Maintenance of functional residual capacity and normocapnia are no longer the main imperatives. Important though these are, it is perhaps ironic that the greatest danger to patients is positive pressure ventilation and volume recruitment, long seen as the salvation for the management of respiratory failure. The breakthrough that has enabled anaesthesia to contribute to the reduction in mortality and morbidity of surgery for respiratory failure is prevention, recognition and treatment of barotrauma and dynamic hyperinflation.

SHORT COMMUNICATIONS

Granisetron reduces the incidence of nausea and vomiting after middle ear surgery

Y. FUJII, H. TOYOOKA AND H. TANAKA

Summary

We studied the efficacy of granisetron, a selective 5-hydroxytryptamine type-3 receptor antagonist, in preventing postoperative nausea and vomiting (PONV) after middle ear surgery. In a randomized, double-blind, placebo-controlled study, 60 ASA I patients received placebo (saline) or granisetron 40 μg kg^{-1} i.v. immediately before induction of anaesthesia (n=30 in each group). A standard general anaesthetic technique was used. During the first 24 h after anaesthesia, the incidence of PONV in patients who had received granisetron was lower than in those who had received placebo (17% *vs* 63%; $P<0.05$). There were no clinically important adverse effects in either group. We conclude that granisetron, given before anaesthesia, reduced the incidence of PONV after middle ear surgery. (*Br. J. Anaesth.* 1997; **79**: 539–540).

Key words
Pharmacology, granisetron. Vomiting, antiemetics. Vomiting, nausea. Vomiting, nausea, surgical factors. Surgery, otolaryngological.

Honkavaara, Saarinvaara and Klemola[1] and Reinhart, Klein and Schroff [2] have demonstrated recently that the incidence of postoperative nausea and vomiting (PONV) after middle ear surgery is relatively high (62–80%) when no prophylactic antiemetic is given. Pharmacological methods to prevent PONV include antihistamines (e.g. hydroxyzine), butyrophenones (e.g. droperidol) and dopamine receptor antagonists (e.g. metoclopramide), but these drugs have undesirable side effects, such as sedation, hypotension, dry mouth, dysphoria, restlessness and extrapyramidal symptoms.[3] Ondansetron, a selective antagonist of 5-hydroxytryptamine type-3 (5-HT_3) receptors, is effective in preventing PONV with little adverse effects.[4] Another 5-HT_3 receptor antagonist, granisetron, is more potent and has longer acting activity against cisplatin-induced emesis than ondansetron.[5] We conducted a prospective, randomized, double-blind, placebo-controlled study to examine the efficacy of granisetron in preventing PONV in patients undergoing middle ear surgery.

Methods and results

After obtaining approval from our institutional Ethics Committee and informed consent, we studied 60 ASA I patients (43 females), aged 20–65 yr, undergoing middle ear surgery (tympanoplasty or mastoidectomy). Patients who had gastrointestinal diseases, who were pregnant or menstruating, or who had taken antiemetics within 24 h before surgery were excluded.

Premedication was not used. Patients were given, in a randomized, double-blind manner, a single dose of placebo (saline) or granisetron 40 μg kg^{-1} i.v., immediately before induction of anaesthesia. Anaesthesia was induced with thiopentone 5 mg kg^{-1} i.v., and vecuronium 0.2 mg kg^{-1} i.v. was used to facilitate tracheal intubation. After tracheal intubation, anaesthesia was maintained with 1.0–3.0% isoflurane (inspired concentration) and 66% nitrous oxide (which was replaced by air before closing of the tympanic membrane) in oxygen. Opioids were not given before tracheal intubation or during maintenance of anaesthesia. Ventilation was controlled mechanically and was adjusted to maintain $P\text{E}'_{CO_2}$ at 4.6–5.2 kPa throughout surgery. Neuromuscular block was produced with vecuronium and antagonized by a combination of atropine 0.02 mg kg^{-1} i.v. and neostigmine 0.04 mg kg^{-1} i.v. at the end of surgery. The trachea was extubated when the patient was awake. If two or more episodes of vomiting occurred during the first 24 h after anaesthesia, standard antiemetic therapy (e.g. metoclopramide) was given. After operation, patients received indomethacin 50 mg orally when they complained of pain.

After operation, each episode of PONV (nausea, retching and vomiting) during the first 24 h after anaesthesia was recorded by nursing staff who had no knowledge of which treatment patients had received.

Table 1 Patient characteristics and incidence of PONV during the first 24 h after anaesthesia. All values are mean (SD or range) or number (%). Statistical analyses were performed using ANOVA, Student's *t* test, chi-square test, and Fisher's exact probability test, as appropriate

	Placebo group (n=30)	Granisetron group (n=30)	*P*
Age (yr)	43.3 (20–62)	44.4 (23–65)	ns
Sex (M/F)	8/22	9/21	ns
Height (cm)	160.1 (8.4)	159.5 (8.0)	ns
Weight (kg)	57.2 (8.6)	56.2 (7.9)	ns
History of motion sickness (n)	3	3	ns
History of previous PONV (n)	2	2	ns
Duration of surgery (min)	213.7 (38.9)	218.2 (41.9)	ns
Duration of anaesthesia (min)	240.2 (37.9)	243.4 (44 5)	ns
Indomethacin administered after operation (n)	16	17	ns
Types of operation performed (n)			
Tympanoplasty	22	23	ns
Mastoidectomy	8	7	ns
PONV during the first 24 h after anaesthesia (n (%))	19 (63%)	5 (17%)	0.001
Nausea	10 (33%)	3 (10%)	0.029
Retching	1 (3%)	0 (0%)	ns
Vomiting	8 (27%)	2 (7%)	0.04

The treatment groups were comparable in characteristics and types of operation. During the first 24 h after anaesthesia, the incidence of PONV in patients who had received granisetron was lower than in those who had received placebo (17% *vs* 63%; P=0.001) (table 1). Six patients who had received placebo required another rescue antiemetic (e.g. metoclopramide) for treatment of two more episodes of vomiting, compared with none who had received granisetron (P<0.05). There were no adverse effects from the test drug in either group.

Comment

The aetiology of PONV after middle ear surgery (tympanoplasty or mastoidectomy) is not known precisely, but is probably associated with several factors. One of these factors is increased middle ear pressure caused by nitrous oxide.[6] Others, including age, obesity, history of motion sickness, previous postoperative emesis, surgical procedure, anaesthetic technique and postoperative pain, are also considered to increase the incidence of PONV.[3] In this study, however, no pressure was generated in the middle ear from diffusion of nitrous oxide which was replaced by air before closing of the tympanic membrane. The treatment groups were similar in characteristics, types of operation, anaesthetics administered and postoperative analgesics used. Therefore, the difference in the incidence of PONV between the groups can be attributed to differences in the drugs tested.

We found a relatively high incidence of PONV (63%) during the first 24 h after anaesthesia in patients who had received placebo. This incidence is in accordance with previous studies by Honkavaara, Saarinvaara and Klemola[1] and Reinhart, Klein and Schroff [2] who demonstrated an incidence of PONV of 62–80% in patients undergoing general anaesthesia for middle ear surgery.

It has been reported recently that granisetron is effective in the prevention of PONV after gynaecological surgery, and its safety profile is good with the recommended dose of 40 μg kg^{-1}.[7] The results of this study showed that the incidence of PONV after middle ear surgery in patients who had received granisetron was less than in those who had received placebo (P<0.05). This suggests that granisetron is effective in preventing PONV after middle ear and gynaecological surgery. The exact mechanism of granisetron in the prevention of PONV is not known, but it has been suggested that it may act on sites containing 5-HT$_3$ receptors with demonstrated antiemetic effects.[8]

This study also showed that six patients who had received placebo required another rescue antiemetic (e.g. metoclopramide) for treatment of two or more episodes of vomiting, compared with none who had received granisetron (P<0.05). Thus granisetron 40 μg kg^{-1} may reduce the severity of PONV after middle ear surgery.

Comparison between alfentanil, pethidine and placebo in the treatment of post-anaesthetic shivering

I. J. WRENCH, G. CAVILL, J. E. H. WARD AND A. W. A. CROSSLEY

Summary

We have compared the effects of pethidine, alfentanil and placebo in the treatment of post-anaesthetic shivering. Ninety patients who shivered after routine surgery were allocated randomly to receive normal saline (n=30), alfentanil 250 μg (n=30) or pethidine 25 mg (n=30). After 10 min, 26 patients had stopped shivering in the pethidine group which was significantly more than the incidence in the two other groups (placebo=7; alfentanil=12) ($P<0.0002$). Alfentanil was not significantly different from normal saline in affecting shivering. We conclude that alfentanil 250 μg was not effective in the treatment of post-anaesthetic shivering. (*Br. J. Anaesth.* 1997; **79**: 541–542).

Key words
Complications, shivering. Analgesics opioid, alfentanil. Analgesics opioid, pethidine.

Post-anaesthetic shivering is a common problem in the recovery room, with detrimental effects including increased oxygen consumption and hypoxaemia.[1] Pethidine has been shown to be one of the most effective treatments for post-anaesthetic shivering.[2–4] Although its mechanism of action is not completely understood, a study using naloxone indicated that pethidine may act via kappa rather than mu opioid receptors. The anti-shivering action of pethidine is inhibited by high-dose naloxone which blocks mu and kappa receptors but not by low-dose naloxone which blocks only mu receptors.[3] Previous work on the efficacy of mu opioid receptor agonists in the treatment of shivering has been conflicting.[2 4] However, in an audit of postoperative shivering it appeared that intraoperative administration of the mu opioid receptor agonist alfentanil was associated with a reduced incidence of postoperative shivering.[1]

In order to investigate further the importance of mu opioid receptors in the treatment of shivering, we have compared the actions of alfentanil and pethidine. Alfentanil 250 μg was used as this is equi-analgesic to pethidine 25 mg,[5] the dose often used to treat shivering.[2] As alfentanil is a more specific mu agonist than pethidine, an equi-analgesic dose should have at least as great an effect on mu receptors. It should also follow that if pethidine acts principally via mu receptors in the treatment of shivering, this dose of alfentanil should be at least as effective.

Methods and results

The study was approved by the local hospital Ethics Committee. We studied 90 patients of both sexes, aged 18–70 yr, who developed shivering in the recovery room. All patients were ASA class I or II and had undergone routine general, orthopaedic, gynaecological or ENT surgery. As a consequence of the patients being selected as they recovered from anaesthesia, their consent was not considered valid and with agreement from the hospital Ethics Committee, informed consent was not obtained. Patients with any contraindications to the use of alfentanil or pethidine were not included.

Routine care for patients in this hospital suffering from postoperative shivering consists of oxygen 4 litre min^{-1} by Hudson mask and covering with a heat reflective blanket. In addition, each patient received an i.v. bolus dose of saline, pethidine 25 mg or alfentanil 250 μg in a total volume of 5 ml. Syringes containing the drug were prepared by recovery room staff after written instructions removed from a sealed envelope. The envelopes were inserted in a random order generated by microcomputer using a shuffling technique.

The investigator giving the i.v. injection was unaware of the treatment received by the patient and assessed the shivering grade before treatment according to a five-point scale: 0=no shivering; 1=one or more of the following: piloerection, peripheral vasoconstriction, peripheral cyanosis without other cause, but without visible muscular activity; 2=visible muscular activity confined to one muscle group; 3=visible muscular activity in more than one muscle group; and 4=gross muscular activity involving the entire body. Tympanic membrane temperature was measured (First Temp

CAVILL, BSC, MB, CHB, FRCA, A. W. A. CROSSLEY, MB, CHB, FRCA, University Department of Anaesthesia, Queen's Medical Centre, Nottingham NG7 2UH. Accepted for publication. May 6, 1997.

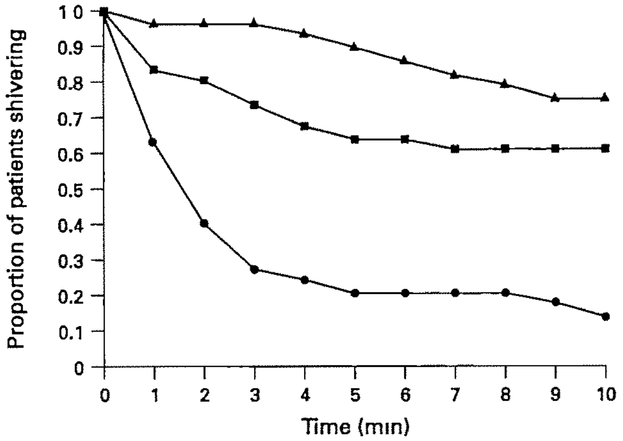

Figure 1 Proportion of patients who continued to shiver at each time in the placebo (▲), pethidine (●) and alfentanil (■) groups (n=28 for the placebo and n=30 for the two other groups). Chi-square analysis at 10 min showed that pethidine was significantly more effective than the two other groups ($P<0.0002$).

Genius Thermometer) immediately before giving the drug and shivering was assessed every minute for 10 min.

From previous work we estimated that a group size of 28 patients was sufficient to detect a 40% reduction in the incidence of shivering relative to placebo with a power of 0.85 at the 5% level.

All three groups had a median shivering grade at entry of 3 (range 2–4). Mean temperature at the time of treatment was similar in all three groups: 36.2 (SD 0.7) for placebo, 36.6 (0.8) for the pethidine group and 36.3 (0.7) for the alfentanil group. None of the patients recommenced shivering after they had stopped. Two patients in the placebo group were excluded as they received morphine for pain relief during the study.

After 10 min, four patients who had been given pethidine continued to shiver compared with 18 in the group given alfentanil and 21 in the placebo group (fig. 1). Chi-square analysis showed that pethidine was significantly more effective than both of the other treatments ($P<0.0002$). Alfentanil did not differ significantly from saline.

Comment

We have shown that alfentanil 250 μg was not significantly different from placebo in the treatment of post-anaesthetic shivering. However, fewer people shivered in the alfentanil group compared with the saline group at every time studied, indicating the possibility that a higher dose may have been more effective. This has been found to be the case with fentanyl; 25 μg (i.e. 0.36 $\mu g\ kg^{-1}$ for a 70-kg man) did not reduce post-anaesthetic shivering[2] whereas 1.7 $\mu g\ kg^{-1}$ (i.e. five-fold greater) was as efficacious as pethidine.[4] As indicated above there is evidence that pethidine may act via kappa opioid receptors in the treatment of this condition. Fentanyl also binds to kappa receptors, although five-fold more weakly than pethidine when binding to mu opioid receptors is used as a reference.[6] It is possible, therefore, that fentanyl, when given in a relatively high dose, acts via kappa receptors to stop post-anaesthetic shivering. This may also be the case for other mu agonists such as alfentanil.

In conclusion, we found that alfentanil 250 μg did not differ from placebo in the treatment of post-anaesthetic shivering. Our results are consistent with the hypothesis that kappa opioid receptors are more important than mu opioid receptors in the treatment of this condition.

CASE REPORT

Thermal softening of tracheal tubes: an unrecognized hazard of the Bair Hugger active patient warming system

J. L. AYALA AND A. COE

Summary

The Bair Hugger system is a new and highly effective active patient warming system which produces a layer of warm air between the patient and the warming system. We report an instance of marked softening and distortion of a polyvinyl chloride tracheal tube caused by this layer. We also present laboratory data indicating that this is a likely problem under routine theatre conditions, with suggestions for prevention. (*Br. J. Anaesth.* 1997; **79**: 543–545).

Key words
Equipment, warming devices. Equipment, tubes tracheal.

Case report

A 61-yr-old man was given a general anaesthetic for left ilio-femoral arterial grafting. He weighed 67 kg and was classified as ASA III because of peripheral vascular disease limiting his exercise tolerance. After i.v. induction of anaesthesia and neuromuscular block, his trachea was intubated with an uncut polyvinyl chloride tube (Mallinckrodt Medical, "Lo-Pro" Magill, 32 cm length, internal diameter 8.0 mm). The tube was connected to a lightweight disposable ventilator system (Armstrong Medical Services Quality Disposable Systems) through a heat and moisture exchanger (HME 10, Pharma Systems AB), forming part of a circle system. The combined total weight of these connections was 275 g, measured by a Mettler PC 24 electronic balance (Mettler Instruments, Zurich). Intermittent positive pressure ventilation was commenced with the following ventilator settings: tidal volume 700 ml, ventilatory frequency 8 bpm and inspiratory flow 30 litre min^{-1}. The "Torso" attachment of the Bair Hugger active patient warming system was attached to the patient, and a model 500 E warming unit (Augustine Medical Inc.) connected and switched on at the 43 °C setting.

Thirty five minutes after surgery commenced, the tracheal tube was noted to have moved from its original vertical attitude to the position shown in figure 1. There was a marked kink in the tube at the corner of the mouth and ventilator peak inflation pressures had increased from 18 to 35 cm H_2O. As the ventilator alarm had been set too widely, responding to peak airway pressures less than 10 and greater than 60 cm H_2O, no alarms were activated. Total obstruction did not occur because of early observation of the problem. To correct the situation, the tube was cut to 22 cm, leaving nothing outside the mouth. The temperature beside the bent tube, with the warm air system working, was 40 °C, as measured using a thermocouple with internal electronic calibration (Hewlett Packard Met 530, HP 21075 A).

LABORATORY STUDY

It was clear that the dangerous tube distortion we had observed was an effect of thermal softening. As active patient warming is in daily use at our institution and as leaving polyvinyl chloride tracheal tubes uncut and self-supporting is common practice, we contacted the tube manufacturers to see if they had any data on thermal softening of their product. Their data related to normal body temperature ranges only. We performed some simple bench tests to investigate the problem.

METHODS

Figure 2 shows the test apparatus used to simulate theatre conditions. It shows a water bath with a tracheal tube anchored in the water and fixed at its other end to some ventilator system tubing and a heat and moisture exchanger. The height of this end of the tube was measured using a fixed vertical scale. A Bair Hugger patient attachment was draped over the tracheal tube and water bath. Tests were carried out in an air conditioned operating theatre with the doors closed. All temperature measurements were made using the same thermocouple thermometer with internal calibration (Hewlett Packard M1029 A). The mean response time for this probe to register stable readings over the full range of temperatures used in the tests was 135 s, measured over five cycles. Calibration of the probe was verified against a platinum resistance wire thermometer in the Process Control Calibration Laboratory at British Steel,

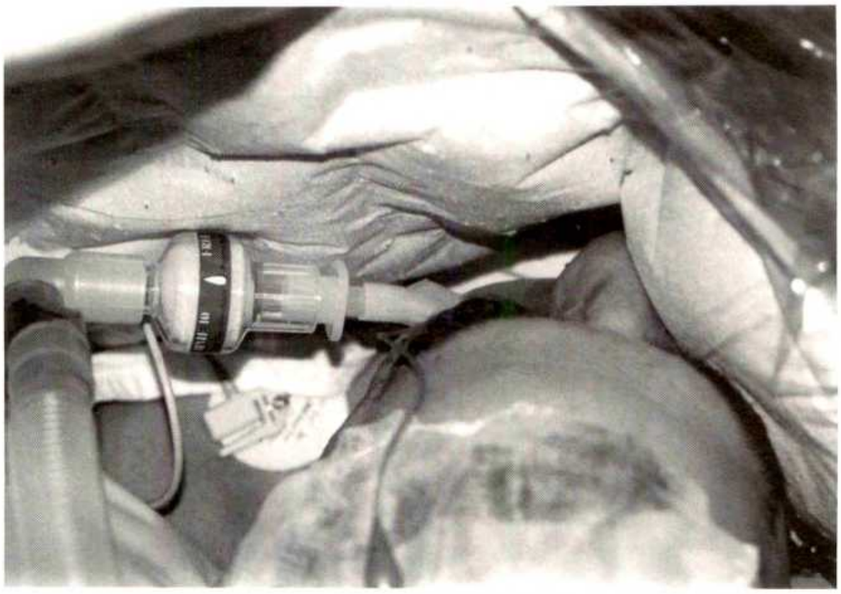

Figure 1 Photograph showing the softened polyvinyl chloride tracheal tube attached to the lightweight disposable system tubing. The tube is displaced 90° from an originally vertical position because of thermal softening.

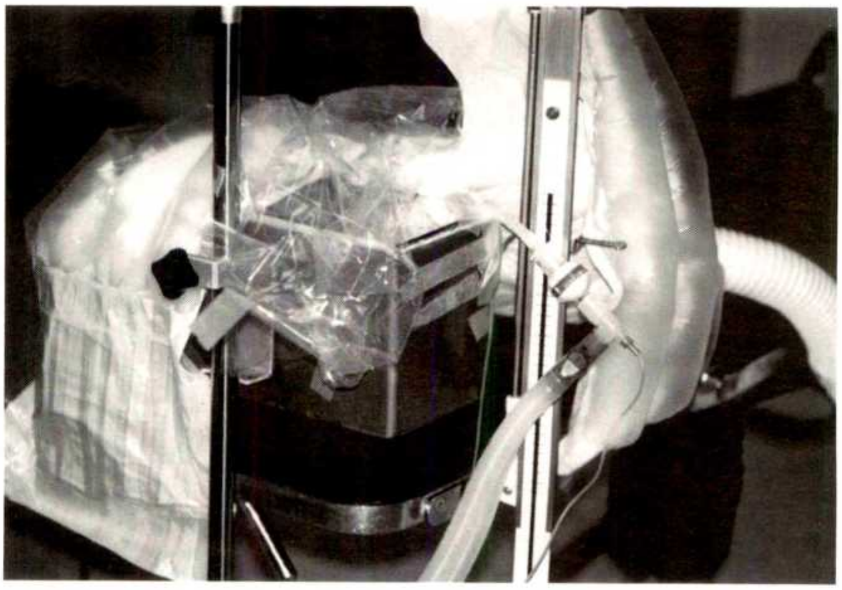

Figure 2 Thermal softening test apparatus rig showing the heated water bath, tracheal tube with displacement scale, and Bair Hugger patient warming attachment.

Scunthorpe. This instrument is checked regularly by the National Measurement Accreditation Service. Air temperature measurements were made by exposing the probe in the room, 100 cm from the apparatus. Water bath temperature measurements were made by suspending the probe in the water bath, at least 5 cm clear of the heating element.

The temperature at the tracheal tube was measured by fixing the probe 1–2 cm from the tracheal tube connector, beneath the heating blanket. The probe was not fixed to the tube itself. Missing temperature measurements in the data tables were caused by delays in obtaining stable, equilibrated temperature readings from the probe.

The water bath represents the patient in this simulation. It was kept as close to body temperature as possible during each test. Each tracheal tube was anchored to the bottom of the bath by passing its distal end through a heavy lithotomy pole bracket and to the side of the bath by adhesive tape. The same system and humidifier described in the case report were attached to the end of each tube. The humidifier was dried between tests. Measurements of deformation were made by noting the starting position on a vertical scale of the lowest point of the tube connector and measuring it again at the end of the test (fig. 2). It was thought that the arc described by this point would be very similar in length to the vertical distance measured, as the radius of the circle of motion was large in relation to the measured

movement. During all measurements, a "Torso" Bair Hugger attachment was draped over the water bath and the tracheal tube under test. This was connected to a Model 500E warming unit. For 50% of the tubes from each batch, the warming unit remained switched off (group C). For the other 50% it was turned on at the maximum setting at the start of the test and left on for the duration of the test (group H).

Twenty tracheal tubes were tested. They were 8.0-mm internal diameter "Lo-Pro" tracheal tubes manufactured by Mallinckrodt Medical, catalogue number 102.80 (as was the tube described in the case report). The batch number of the first 10 sample tubes were 12.94 4692 and of the other 10, 02.95 5654. Five tubes from each batch were used in each test group. For each tube, measurements of temperature adjacent to the tube under the Bair Hugger attachment were made at zero, 15 and 30 min from the start of the test. Measurements of water bath temperature and tube deformation were made at 15 and 30 min into the test, and room temperature was measured at 15 min (table 1).

RESULTS

The Student's *t* test was used to analyse the data. Table 2 shows the results. There were no significant differences between the water bath temperatures and room temperatures recorded in the two groups. Mean tracheal tube deformation was significantly greater ($P<0.001$) in group C (7.5 mm) than in group H (21 mm). The tubes in group H were deformed to a greater extent.

Discussion

Active patient warming using a forced-air mattress system is a widely used and well documented technique for routine theatre purposes.[1–3] The system is relatively new and research has focused largely on comparison with existing or alternative warming techniques.[1 4] Apart from routine manufacturer's warnings, we were unable to find any published data on potential hazards.

In this case report, we noted marked thermal softening of a polyvinyl chloride tracheal tube caused by exposure to the warm air layer produced by a Bair Hugger active patient warming system. Our laboratory data indicated that this is a likely occurrence under routine theatre conditions.

In summary, tracheal tubes were warmed markedly when a Bair Hugger warming apparatus was used. The tracheal tube softening that this produced presents a threat of obstruction to the tube. The use of uncut PVC tubes is not recommended when this warming system is used. If uncut tubes are used, they must be supported adequately. High and low thresholds of pressure sensitive ventilator alarms must be set close to peak inflation pressure to give immediate warning of any obstruction.

CORRESPONDENCE

Low-dose dopamine: there is a scientific rationale

Sir,—Regarding the recent editorial "Low-dose dopamine: will there ever be a scientific rationale?",[1] I do not question its content, but rather what should have been included.

It is expressed clearly and well justified that low-dose dopamine probably does not save lives in intensive care units. The authors briefly mention that dopamine "...limits adenosine triphosphate utilization and oxygen requirements in nephron segments, at least for ischaemic injury....". This point is important for the justification of the use of dopamine in the protection of the kidney during a relatively short-lasting (hours) or severe ischaemic insult. This idea is derived from some anatomical and physiological characteristics of the medulla. Within the medulla, oxygen diffuses from arterial to venous vasa recta which predisposes the outer medulla to a degree of oxygen deprivation. In this region the medullary thick ascending limb of Henle's loop (mTAL) is responsible for the creation of an osmotic gradient by reabsorption of sodium. This process demands and consumes a significant amount of energy and oxygen. The rate of reabsorption at the level of mTAL is the main determinant of renal oxygen demand, and suppression of reabsorption is associated with a significant increase in medullary oxygen tension.[2] A well documented, dopamine-induced anti-aldosterone effect[3] and inhibition of Na^+–K^+-ATPase results in a decrease in solute reabsorption[4 5] and subsequently a decrease in oxygen demand in the tubules, particularly in the mTAL, the most vulnerable part of the nephron to ischaemic insult.[6–8] In addition, dopamine increases the formation and release of prostaglandin E_2[9] which dilates medullary vessels[10] and also inhibits oxygen consumption in tubular cells.[11] An increase in renal blood flow resulting from activation of DA-1 receptors might improve renal function (renal blood flow, glomerular filtration rate (GFR), sodium and water excretion) in patients with acute renal insufficiency,[12 13] however, the increase in GFR *per se*, which represents an "improvement in renal function", might be detrimental for the viability of the kidney undergoing a short but severe ischaemic insult (e.g. suprarenal aortic cross-clamping). An increase in renal cortical blood flow and GFR would be associated with an increase in transport of the solute to the tubules, an increase in reabsorption and oxygen demand.

This scientific rationale for the use of dopamine (in conjunction with other drugs decreasing reabsorption) has not enjoyed overwhelming confirmation by clinical data. There are probably many reasons for this. One may be that there is a narrow window of opportunity where any therapeutic intervention can be proved by outcome studies. In other words, the majority of patients would not need any treatment and their renal function would be preserved after a relatively short ischaemic insult; or, for some patients, the ischaemic insult would be so severe that none of the treatments could be effective. The situation can be aggravated by the different baseline status of renal function and reserves. One study of the prophylactic use of dopamine demonstrated a significant decrease in the incidence of renal insufficiency in patients undergoing angiography with impaired baseline renal function, while there was a difference in patients with relatively normal renal function.[14] Thus despite the lack of clinical data, present scientific literature seems to justify the rationale that low-dose dopamine in addition to (or in conjunction with) some other loop diuretics might protect the kidneys during ischaemic insult.

External cooling in critically ill febrile ICU patients

Sir,—The findings of Poblete and colleagues[1] indicate that external cooling is more effective than antipyretic agents in the treatment of febrile ICU patients. As the authors noted, application of ice sponges is relatively inconvenient and the method of external cooling used in the first instance by many ICU is the rotary fan. However, an extensive literature search has revealed no studies on the efficacy of this method in these circumstances. In addition, increased risk of airborne infection is a potential concern. Fans are unlikely to act as a source of infection in the way that contaminated air conditioning systems can[2 3] but they might enhance transmission of airborne pathogens between adjacent patients. Environmental contamination of the ICU with pathogenic bacteria is well known[4] and in one ICU inadvertent circulation of air from an isolation room back into the main unit led to an outbreak of methicillin-resistant *Staphylococcus aureus*.[5] Given the ineffectiveness of antipyretic drugs demonstrated by Poblete and colleagues, further studies on the efficacy and risks of other antipyrexial therapies used in the ICU seem warranted.

Inhaled nitric oxide

Sir,—The Intensive Care Society recently published recommended safety precautions for the therapeutic use of inhaled nitric oxide (Winter 1996 newsletter). Included in these was a suggestion that when high concentrations of nitric oxide are used in areas of limited ventilation, a scavenging system should be used. A footnote added that activated charcoal absorbers were ineffective scavengers of nitric oxide. This information seems to have come from an article by Squire, Kightley and Petros[1] where the authors stated "using activated charcoal...no reduction in exhaust gas concentration was detected at any time".

We recently had reason to test if "Aldasorber" (Shirley Aldred and Co. Ltd, Bradwell, UK) activated charcoal scavenging units absorb nitric oxide. A nitric oxide mixture containing 40 ppm of nitric oxide was passed through an Aldasorber unit at 10 litre min^{-1}, and the effluent nitric oxide concentration was recorded with a chemiluminescence analyser linked to a personal computer recording at 6-s intervals. The analyser has a limit of detection of 0.05 ppm and a display resolution of 0.1 ppm in the range used. When the carrier gas was nitrogen alone, nitric oxide appeared at the outlet of the absorber almost immediately, and reached a maximum of approximately one-third of the inlet concentration (fig. 1). When the carrier gas was air, nitric oxide was detected in the effluent gas only after 13.2 h, and at 24 h the effluent concentration was only 0.1 ppm. When 40 ppm of nitrogen dioxide in nitrogen were passed at 10 litre min^{-1} through an absorber, no nitrogen dioxide was detected in the effluent gas over the 1-h period of the experiment.

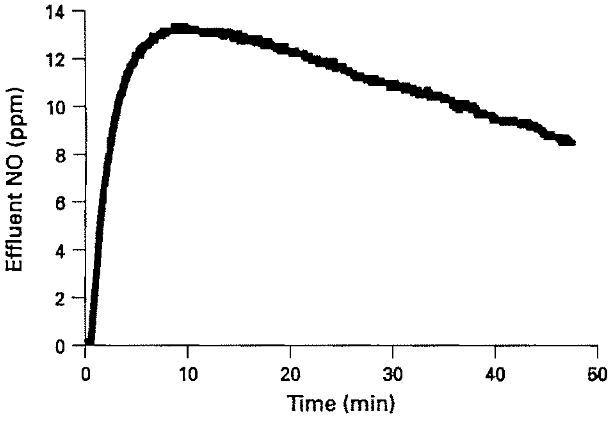

Figure 1 Effluent nitric oxide (NO) concentration when an NO mixture containing NO 40 ppm was passed through an Aldasorber activated charcoal scavenging unit.

The discrepancy between these results and those of Squire, Kightley and Petros[1] is difficult to explain. They used Carbomix (Penn Pharmaceuticals Ltd, Gwent, UK) as an absorber, a charcoal designed to be mixed into a slurry and instilled into the stomach to absorb drugs in the aqueous phase. This formulation is approximately 80% charcoal; the remainder is citric acid, acacia gum and glycerine. This presumably alters the gas absorbing properties of the charcoal. Aldasorber units are designed to remove organic anaesthetic agents in the gas phase.

Our results suggest that nitric oxide is scavenged by activated charcoal, but only in the presence of oxygen. As nitrogen dioxide is scavenged even without oxygen, it is possible that the charcoal catalyses the oxidation of nitric oxide to nitrogen dioxide which is then absorbed. Whatever the mechanism, activated charcoal would appear to be an effective scavenger of nitric oxide at concentrations used in clinical practice.

Predominant involvement of motor fibres in patients with critical illness polyneuropathy

Sir,—Hund and colleagues demonstrated that critically ill patients may suffer from an acute axonal motor polyneuropathy which is related to sepsis, and not to the use of neuromuscular blocking agents.[1] This result has important nosological implications because the reduction in compound motor action potential (CMAP) with preserved sensory action potential has until now been taken as evidence in favour of neuromuscular blocking agent-related neuropathy (or myopathy) and against critical illness polyneuropathy (CIP).[2] However, three aspects of this study need clarification.

First, seven of 20 patients with grade 2–3 denervations were found to have CIP and normal CMAP amplitude (fig. 1[1]). This was a strange result. In axonal neuropathy the total number of nerve fibres is reduced, while myelination of surviving fibres is maintained. Therefore, CMAP amplitude (which is the sum of the action potentials of all nerve fibres) decreases while nerve conduction velocity remains normal or nearly normal. CMAP, an energy-requiring event, may be reduced at an early stage of sepsis and critical illness. In contrast, signs of denervation take several days or weeks to become evident.[2] Therefore, it would be theoretically justifiable to have reduced CMAP without signs of denervation, but the opposite situation would not be possible. In the discussion the authors stated that "these 20 patients had abnormal CMAP".

Second, it was suggested that mild CIP is unlikely to cause weaning failure. However, mild CIP of the limbs does not necessarily imply mild CIP of the diaphragm and respiratory muscles, and it would be worrying for intensive care physicians to assume that neuromuscular problems are not ongoing without carefully assessing respiratory muscles and nerves.[3]

Finally, the authors stated that myopathy was an unlikely diagnosis in their patients because creatine kinase concentration (CK) was mostly normal and asthma was not a cause of admission. Diagnosis of myopathy in critically ill unconscious patients requires muscle biopsy for confirmation. CK may remain normal but the muscle may be electrically inexcitable.[4] An electrophysiological study is not conclusive in itself. In fact, CMAP may be reduced because of motor neuropathy, myopathy or both. Furthermore, denervation signs may be seen also in myopathy when the necrotic process disconnects the end-plate zone from the active membrane.[5] We have shown that many septic patients with an electrophysiological diagnosis of CIP had a myopathy at biopsy.[6]

Sepsis does not spare muscle and critical illness myopathy is at least as frequent as CIP,[6] provided the correct investigations are used. If biopsy is not planned, diagnosis of neuromuscular disorder would be more appropriate.

Sir,—Thank you for the opportunity to respond to the comments of Drs Latronico and Candiani. As in other studies, CIP was defined in our study as newly occurring pathological spontaneous activity in resting muscles during ICU treatment.[1 2] Although CMAP amplitudes are usually reduced, we encountered patients who had normal CMAP amplitudes despite severe denervation activity on EMG. For example, in patient No. 14, who had severe sepsis after major abdominal surgery, median nerve CMAP amplitude was 8.1 mV and SNAP 22 µV at the time of grade 3 denervation activity in all muscles examined. Patient No. 17, with polytrauma and severe head injury, had a median nerve CMAP of 6.0 mV and SNAP of 84.9 µV (*sic*) shortly before death. In this patient, grade 3 denervation was present for 2.5 weeks. The reason for this finding is unclear. So far the exact mechanism and type of lesion in CIP has not been elucidated. Thus when confronted with CIP, one should bear in mind that classical polyneuropathy, characterized by dying-back type axonal degeneration, is most likely not involved. Evidence for other mechanisms comes from electrophysiological studies and the observation that recovery is often very fast, that is much faster than expected in chronic axonal degeneration.[3]

Among the many authors reporting on CIP, only Bolton advocates phrenic nerve conduction studies and electromyography of the diaphragm.[1] Until now, his group has published one series in which such studies were included.[4] In this series, four of 16 patients with bilateral phrenic neuropathy had mild CIP according to electrodiagnostic examination of the limbs. One of these patients also had abnormal central respiratory drive. The degree of phrenic nerve involvement and diaphragmatic denervation was not quantified. Although we cannot exclude the possibility that some of our patients had significant phrenic neuropathy despite only minor abnormalities of the limbs, we feel that this is quite unusual in a generalized disorder such as CIP. We agree, however, that diaphragmatic EMG and phrenic nerve conduction studies should be performed in patients with persistent failure to wean, if repeated limb electrodiagnosis shows only minor abnormalities.

We discussed the issue of myopathy in our article. Most authors diagnose patients as having CIP without performing muscle biopsy. In general, such florid denervation activity, as observed in patients with CIP, is unusual in myopathy. After the advent of the report of Rich and colleagues,[5] we included testing of electrical excitability of muscles in our protocol. So far none of our patients has been found to have electrically inexcitable muscles (unpublished result). Latronico and colleagues had a high number of patients with myopathic features on histopathological examination who were diagnosed as having only CIP on the basis of electrodiagnosis.[6] However, all but two patients biopsied late in the disease course had histopathological findings consistent with the electrophysiological results. Thus in the later stages of sepsis, electrodiagnosis alone may give reliable results, while in the early disease state, muscle biopsy may be necessary for a correct diagnosis.

BOOK REVIEWS

Applied Cardiovascular Physiology. (Update in Intensive Care and Emergency Medicine Series). M. R. PINSKY (editor). Published by Springer, Berlin. Pp 263; indexed: illustrated.

This is a slim volume in the series from Springer, *Update in Intensive Care and Emergency Medicine.* It is a multi-author text and is aimed at those providing acute medical care.

The book is divided into four sections: basic cardiovascular physiology, clinical applications, goals of resuscitation and cardiovascular support by haemodynamic subset.

The first section, on cardiovascular physiology, is the longest in the book and provides good coverage of both established concepts in cardiovascular physiology and some newer ideas. The chapter on left ventricular function gives an excellent readable account of left ventricular haemodynamics. That on AV coupling is a useful introduction to the application of engineering concepts to this problem in haemodynamics. The discussion of the cardiovascular management of the critically ill patient is excellent and provides a valuable account of the mechanism and impact of various cardiovascular manipulations. I found the account of the effect of stressed and unstressed volume on venous return particularly useful.

The second section, clinical applications, deals with issues in haemodynamic monitoring. Many of the concepts on invasive haemodynamic monitoring are already known to many readers but this chapter contains useful material. The distinction between wedge pressure and pulmonary artery occlusion pressure is well made. There is a good considered review of the value of trans-oesophageal echocardiography which many readers will find of value as this technique becomes more widespread. One criticism of this section is that the discussion of the rationale for haemodynamic monitoring tends to avoid the vexed issue of the lack of studies which show an impact of haemodynamic monitoring on outcome and chooses to emphasize the perhaps self-evident fact that such monitoring allows cardiovascular manipulations to be undertaken.

The third section, goals of resuscitation, introduces the relationship between Do_2 and Vo_2, which is a major theme in the remainder of the book. The nature of the relationship and its physiological and pathophysiological basis are dealt with at length. The current uncertainty regarding supranormal haemodynamic targets is well discussed.

The final section on cardiovascular support by haemodynamic subset aims to focus attention on important aspects of cardiovascular support in various types of cardiovascular failure. The chapter on cardiogenic shock is excellent. That on septic shock is to some extent a catalogue of the effects of different cardiovascular drugs and I found it heavy going. The final chapter on extracorporeal support was somewhat lacking in detail. There was a conspicuous absence of any discussion of the lack of randomized controlled studies showing benefit from extracorporeal techniques in adults.

I have two criticisms of this book, both minor. The book focuses on the impact of physiological interventions on the cardiovascular system rather than on outcome. However, there is some discussion of the effect of interventions on outcome and this is primarily a physiology text. More importantly the book would have benefited from more rigorous editing and proof reading. In some chapters the use of English is strained and there are significant numbers of duplicated words and other grammatical errors.

On balance, this is an useful book. It is not a text for the examination candidate but will be of interest to the established practitioner. It is slim enough to be read from cover to cover. The specialist in intensive care or cardiovascular anaesthesia will find much which is valuable and the generalist will certainly find information of interest.

S. J. Howell

Principles and Practice of Pharmacology for Anaesthetists, 3rd Edn. T. N. CALVEY AND N. E. WILLIAMS. Published by Blackwell Science, Oxford. Pp. 596; indexed; illustrated. Price £75.00

This is the third edition of a book which has long been popular with candidates preparing for FRCA examinations. In the 6 yr since the second edition was produced there have been several new drugs introduced and advances in the theories of drug action The authors have revised and updated all of the chapters although the overall format remains the same.

The book contains 17 chapters, each 30–40 pages long The book can be divided into three, roughly equal sections. The first section has six chapters on general pharmacology which covers drug uptake and elimination, pharmacokinetics, drug action, isomerism, drug interactions and variability in drug response. The second section covers anaesthetic drugs and in five chapters deals with i.v. anaesthetics, inhalation agents, local anaesthetic agents, drugs acting on the neuromuscular junction and analgesic drugs. The final section deals with drugs acting on other systems and includes six chapters on the autonomic nervous system, premedication and antiemetics, antihypertensives, anti-arrhythmic and anti-anginal drugs, anticoagulants and corticosteroids, and hypoglycaemics. There are no specific chapters on the respiratory, gastrointestinal or renal systems. However, the majority of these drugs are covered within some of the aforementioned chapters. For example, asthmatic drugs are covered in the autonomic nervous system and diuretics under antihypertensive drugs (although one would not usually expect to find mannitol under such a heading).

Individual chapters are clearly divided into appropriate sections. At a glance the text for each drug would appear to be short but on reading it it is clear that it is packed with facts. Hence while the text is not that of a comprehensive reference textbook it is appropriate for those studying for examinations. There are relatively few figures but those that are included are clear and comprehensive, and link well with the text. The text is not referenced but each chapter provides a list of about 50–60 articles for further reading. The majority of these are from the 1980s, perhaps reflecting the age of most of the drugs described, but references up to 1996 are included. Overall, I think this book will justifiably remain popular with candidates preparing for FRCA examinations and will also be a useful quick reference book for practising clinicians.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 79, No.5 NOVEMBER 1997

EDITORIAL I

"Walking extradurals" in labour: a step forward?

The ideal analgesic drug or technique for use in labour should be simple and safe to administer with no adverse short- or long-term effect on the mother, no effect on progress of labour and have either a beneficial effect or no effect on the fetus. Most importantly, it should decrease or abolish the pain of labour without affecting other sensations such as the desire to push. Such an analgesic or analgesic method does not exist. Until recently, extradural administration of local anaesthetic solutions have been used to abolish the pain of labour but a proportion of women find the motor block produced by such solutions unacceptable.[1] In addition it has been suggested that extradurals are associated with long-term back pain,[2 3] and increased Caesarean -section[4] and instrumental delivery[5] rates. However, all of these associations have been vociferously challenged.[6–9]

Complete motor block is not an inevitable consequence of extradural analgesia.[10] Several techniques have been used to reduce or even abolish this in an attempt to produce selective nociceptive block. In evaluating such techniques it should be established if the objective of treatment is to allow movement in bed or normal walking. Walking in labour, considered here, with good extradural pain relief, is possible and is associated with a greater degree of maternal satisfaction than non-mobile techniques.[11] The fact that demand for extradurals has increased dramatically in hospitals where ambulatory extradurals have been introduced has implications for anaesthetic workload and staffing.[1]

The adoption of the recumbent position (wedged supine) throughout labour facilitates monitoring of the mother and fetus. However, it may also have adverse effects on duration of labour, requirements for analgesia, fetal heart rate abnormalities and the chance of operative delivery, although this is controversial.[12] Some authors have strongly criticized the treatment of women in labour as ill patients[13] and the adoption of the recumbent position in a hospital bed may contribute to this attitude. Relatively few studies have specifically encouraged walking, but if this is the objective of treatment then it may involve additional risks while providing benefits other than preserving motor power.

Cardiotocograph (CTG) monitoring of the fetus in women who are mobile is difficult but telemetric CTG devices are available commercially. In some centres the CTG is only intermittently monitored routinely in walking women receiving extradural analgesia with no apparent adverse effect.[14] However, other authors have described CTG abnormalities after intrathecal administration of sufentanil to women in labour and recommend the use of continuous monitoring for 1 h after administration.[15]

The requirements of safe walking with regional block are muscle power, proprioception and a subjective feeling of ability to walk,[1] in addition to vision and an intact vestibular apparatus.[16] Surprisingly, many authors have allowed mobilization based solely by testing power against resistance while recumbent, such as straight leg raising,[11] the Medical Research Council (MRC) score[17] and Bromage[18] score. After one of their patients fell with no detectable weakness on the Bromage scoring system, Breen and colleagues[19] modified the assessment to include a partial knee bend. This may be a more appropriate assessment because it tests dynamic power of the hips, knees and ankles which are involved in lifting the subject's own weight. Buggy, Hughes and Gardiner[20] concluded that patients who had apparently normal power (assessed by MRC score), some of whom felt able to walk, should not be allowed to do so because of significant posterior column sensory impairment resulting in proprioceptive loss. Others have noted that proprioception is not necessary for walking, providing that vision and motor power are preserved,[16] and that the doses of extradural drugs used by Buggy, Hughes and Gardiner[20] were significantly greater than those used by other authors who advocated walking.[21] Posterior column function has been assessed subsequently in more appropriate "walking extradurals" and found to be preserved.[22 23] It is unclear what tests are required. A modified Bromage score of 6 (partial knee bend while standing),[6] a test of proprioception such as Romberg's sign and a supervised trial walk would seem to be the minimum test requirements. In any event, women should be supervised at all times and their walking supported with an appropriate adult in case of unsteadiness.[10]

The effects of supine hypotension caused by aortacaval compression on the mother and fetus are well known and the extremes of lateral tilt required to abolish it have been described previously.[24] It is possible that the upright position further attenuates aortacaval compression, reducing the effects of venous pooling on maternal arterial pressure and fetal heart rate in the standing position.[25] The effect of analgesia in walking mothers on mode of delivery is unclear but there is some evidence that reducing motor block and encouraging walking is associated with a decreased rate of instrumental[26,27] and operative delivery.[28] In other studies this difference was not statistically significant.[29] A pilot study showed a non-significant increase in normal delivery rates in women who had received "walking extradural" analgesia who were allocated randomly to stand or stay supine 1 h before pushing in the second stage of labour.[30]

Studies that have been designed to encourage walking usually rely on institution of analgesia with a mixture of low-dose local anaesthetic and opioid administered into the extradural or subarachnoid space followed by a further mixture given into the extradural space. A well described technique in the UK is a combined spinal–extradural (CSE) technique using a subarachnoid dose of 2.5 mg of plain bupivacaine and 25 μg of fentanyl, followed by extradural boluses of 10–15 ml of bupivacaine 0.5–1 mg ml^{-1} and fentanyl 2 μg ml^{-1}.[14] Other opioids such as sufentanil[29] (not available in the UK) and alfentanil[31] have also been used. Studies are awaited using ropivacaine and L-bupivacaine which may further reduce motor block associated with extradural analgesia. Other studies have included administration of α_2 agonists such as clonidine or adrenaline, in some cases without the use of local anaesthetic,[32] although the role of these agents in labour is unclear.

The main advantages of initial subarachnoid administration of an anaesthetic mixture are speed of onset of analgesia (usually within 5 min of administration)[11,33] and increased maternal satisfaction. It has been suggested that this initial dose reduces subsequent requirements for analgesia and therefore preserves the ability to walk in late labour.[1] Possible disadvantages are a relatively high incidence of failure to puncture the dura with the spinal needle[1]; this occurs in approximately 5–10% of cases using the "needle through needle" CSE technique, despite correct placement of the Tuohy needle in the extradural space.[1,11,14,34] It is possible that routine dural puncture with the spinal component of CSE may produce an increased incidence of post-dural puncture headache (PDPH)[34] but the pencil-point needles used are associated with a relatively low rate of headache.[35] An initial high rate of PDPH reported by workers at Queen Charlotte's Hospital was not evident in subsequent studies.[1,11,14] In a study where the incidence of dural puncture was extremely high, puncture with the Tuohy needle occurred less often during CSE than with extradural insertion alone (1.7% *vs* 4.2%).[34]

Another problem reported with CSE is subsequent insertion of the extradural catheter into the CSF after dural puncture with the spinal needle.[36] A cadaveric study using Quincke-tipped needles showed that this was virtually impossible.[37] Such cases are more likely to have occurred through inadvertent dural puncture with the Tuohy needle and therefore the risk of subarachnoid catheter insertion is the same whether CSE or extradural alone is used. The first use of any extradural catheter must be under the direct supervision of personnel able to manage the consequences of inadvertent subarachnoid administration, particularly where an extradural catheter "test dose" has not been given.

Cases of meningitis have been reported after CSE.[38] Apparent risk factors include chemical contamination of equipment with sterilizing fluid and multiple extradural and dural punctures. The many causes of aseptic and septic meningitis after central blocks have been reviewed recently in an editorial which may reassure proponents of CSE.[39] However, even a relatively low excess incidence of associated meningitis in routine clinical practice would make any new technique unacceptable.[40]

The subarachnoid component of CSE provides analgesia superior to an extradural alone particularly when used in late labour and may preserve the ability to walk in late labour. However, the disadvantages, which are not insignificant, have caused several authors to question the routine use of dural puncture to facilitate analgesia in labour[40,41] and this is the subject of several studies in progress.

Maintenance of extradural analgesia may be provided by continuous infusion, patient-controlled extradural analgesia (PCEA) or traditional boluses. A significant advantage of mechanical administration of extradural mixtures by infusion or PCEA is that in many centres in the UK midwives are not allowed to administer boluses of mixtures of drugs[42,43] into the extradural space. Infusions are associated with a greater incidence of motor block in late labour because administration of local anaesthetic may be greater than a patient's requirements.[44] If mobility is important in late labour[30] then gradually increasing motor block would be a disadvantage with infusion-based techniques. A criticism of PCEA in walking women is the possibility of receiving a self-administered bolus of extradural solution in the absence of a midwife.[41] The use of extradural infusions but not PCEA has been associated with a greater need for medical assessment and administration of analgesia.[43,45,46] Some authors have found PCEA pumps unreliable in a walking population.[47] Significant advantages of PCEA are increased maternal satisfaction, feelings of self-control and a dose-sparing effect compared with continuous extradural infusion.[43,46]

Many hospitals in the UK have provided extradural services for decades with conventional extradurals. The fact that their side effects are so controversial, and serious side effects such as death or major neurological sequelae are so rare provides evidence for the inherent safety of the technique. It is possible that "walking extradurals" are associated with side effects which may preclude their use in labour. If any new technique is to be introduced it needs to be evaluated carefully first to establish any superiority and second to monitor side effects. In their first series of patients, workers at Queen Charlotte's Hospital found an initial high incidence of side effects such as PDPH and these diminished with time.[1,11,14] This would indicate that such techniques are not for occasional use by inexperienced personnel.

Mobile extradural techniques have the potential to provide pain free, enjoyable labour with possibly more chance of normal delivery and fewer long-term side effects than conventional extradurals. The case for the widespread use of such techniques has not yet been made. Further work is necessary to establish the benefits of such procedures and to justify the routine use of dural puncture in all women requesting central block in labour rather than extradural administration alone. To date the only convincing evidence is that CSE is associated with increased maternal satisfaction and earlier onset of analgesia.

EDITORIAL II

Anaesthesia and the competence revolution

An assessment is what we do when we wish to measure the outcome of an episode of learning. It may take many forms such as an examination, a multiple-choice questionnaire (MCQ), an oral examination, an objectively structured clinical examination (OSCE) or a workplace observation. Every assessment should conform to a simple set of rules: it must have a purpose, an outcome, validity and reliability. A valid assessment is one that measures what it is supposed to measure. A reliable test is one that produces the same results if the candidate immediately retakes the test and irrespective of which examiner marks it. An assessment also expresses something about the philosophy of education and learning. Traditional academic education is associated with the view that learning trained the mind in ways that were of general benefit to future performance. This view of "liberal education" was expressed by Cardinal Newman (1852)[1]: "Even though it be turned to no further account, nor subserve any direct end... To open the mind, ... to refine it, ... to give it powers over its own facilities is an object as intelligible as the pursuit of virtue."

Despite the lack of evidence to support the connection between academic accomplishment and success in the workplace[2 3] the government and public equate examination passes with excellence. Many examinations in medicine seek to explore deep understanding of underlying concepts and do not try to test the ability to do a job. Recently there has been a move within general education towards learning and assessment that are focused on the ability of the learner to do the job. These changes towards "competency based education" are fundamental enough to amount to a paradigm shift in education. In this new educational model, assessment is by direct observation of competence. The issue was expressed clearly by Jessop: "Assessment of performance in the course of normal work offers the most natural form of evidence of competence and has several advantages, both technical and economic."[4]

The competency based training revolution began in the USA during the mid-1960s. The quality of teaching in schools was criticized and many felt that the curriculum for teacher training bore little relationship to the job requirements of teaching.[5] With federal government sponsorship several colleges began to teach student teachers according to a new competency based curriculum. This concentrated on skills for the classroom. Assessment became practice based and centred around observation of skills in action.[6]

In the UK during the early 1980s the idea of competency based training suited the government's thinking on education. There had been massive increases in youth unemployment and many employers felt that school leavers lacked the type of skills needed for work. Vocational education in the UK was compared unfavourably with that in other developed countries and government became convinced that reforms were needed. A succession of vocational courses, the New Training Initiative, Btec, NVQ and GNVQ has followed. Competence based learning appealed to the architects of these new qualifications. In the words of the Deputy Director of the National Council for Vocational Qualifications: "The measure of success for any education and training system should be what people actually learn from it, and how effectively. Just common sense you might think, yet this is a comparatively new idea."[4]

Vocational courses are concerned with teaching skills that have direct application in employment but many of its champions have sought to bring about a shift in education beyond this limited purpose. They see learning in terms of changes in behaviour. These changes are termed learning outcomes and are defined in a new type of syllabus which, instead of listing what is to be learned, concentrates on the skills, knowledge and understanding the learner will have at the end of the course. The new vocational curricula list learning objectives in great detail.

The competence model of the curriculum is linked to a new view of assessment. Traditionally a test is successful if it reliably returns a candidate's score in terms of a pass mark. Good teaching and learning leads to a pass in the test. In the new thinking the success of a test is defined in terms of how well a "pass" guarantees future good performance when the new knowledge is put to work. Clearly the examination hall has a reduced role in this type of testing and observation of the trainee in action becomes important. The expected outcomes of learning are defined as new competencies that can be assessed in action.

Medical education is vocational. Traditionally the curriculum has been academic in nature and a major emphasis in testing has been on traditional examinations. Practice has been taught alongside theory and efforts have been made to integrate the two to ensure the overall competence of graduates. New methods of teaching medical undergraduates have concentrated on learning outcomes in broader terms than success in academic examinations. Problem based learning is in some aspects a performance based approach to education. The curriculum concentrates on encouraging the skills of medical practice. Problem solving uses decision making skills and teachers hope to improve clinical reasoning. Learning outcomes are defined in terms of changed behaviour and assessment makes greater use of observation of behaviour. Learning and assessments are closely coupled and education is holistic. The use of competency teaching and assessment is now being promoted in medical education.[7]

So the tide is at the door and competency lead, performance based approaches to anaesthetic education are being seen. The *Objectives of Training in Anaesthesia* of the Australian and New Zealand College of Anaesthetists[8] are written in competency terms. The syllabus provided by the Royal College of Anaesthetists[9] is not as directly competence orientated but the changed emphasis is clear. So it seems the tide is not just at the door but already up to our necks. It is pertinent to wonder if anaesthetists understand what a change towards competence based learning implies.

Competence based learning will be associated with workplace competence testing. National examinations are intended to ensure that new entrants to specialist practice have reached an acceptable standard. They focus primarily on knowledge that can be tested by the type of assessments that are practicable, fair and consistent when applied to large groups of candidates.[10] Practical skills, behaviour and personal qualities are not amenable to formal examination testing. These qualities are none the less, important in determining if an anaesthetist is effective. Unfortunately practical clinical competence assessment is very difficult to perform. Assessment involves generalizing from an observation that has been made in the course of work; only if this generalization holds up in practice will the assessment be valuable. The sample of professional behaviour observed must be representative of all related behaviours.[11 12] Here is an immediate problem with the assessment of clinical competence. We do not know how wide a spectrum of behaviours we must observe in order to make valid overall conclusions.

A further difficulty is in deciding how to score an observation. An assessor can watch a trainee in action and then allocate a mark for competence. This approach is totally subjective and the assessments are likely to show poor reliability. Several approaches have been used to improve the objectivity of scoring. The examiner can score the trainee in several "domains". The scoring relies usually on a verbal rating between poor and very good. This approach at least indicates to the trainee the type of problems that the assessor is detecting. Greater consistency may be achieved by using a check list of observations that again can be related to domains. This makes some effort to ensure that the trainee is doing everything that should be done. An alternative means of conducting an observational assessment is by critical incident identification.[13] The trainee is observed and good and bad examples of practice are noted. A subsequent analysis of these according to predetermined criteria allows a score to be allocated. Modifications of Flanagan's technique which was originally developed for aircrew training have been used widely in medical[14–17] and nurse[18] education.

A more fundamental criticism of setting learning outcomes and then observing competencies is that this underrates the complexity of the professional task. Administering an anaesthetic can be divided into a sequence of competencies that are easy to see. Usually the trainee performs adequately in all steps of the sequence but this is no guarantee of competence. The progress of anaesthesia is not a succession of learned behaviours; it is based on complex cognitive skills expressed as clinical reasoning. Observing progress of anaesthesia does not easily reveal if the underlying reasoning is sound. The trainee may be running through an impoverished repertoire of behaviours and responses that are not flexible enough or deep enough to carry across into new situations. Sivarajan and colleagues found no correlation between clinical performance and knowledge in a spinal anaesthesia skill test.[19]

There is very little literature relating to the assessment of anaesthetists[20] and most of this makes no reference to how an observational assessment in the workplace can be done in ways that provide valid and reliable results. There is an obvious need for careful evaluation of available means of measuring clinical competence. It is necessary to develop tests that are reliable. This will not be easy. Even more important is consideration of the validity of the tests. There is a danger that competence testing will concentrate on the surface behaviour of the trainee without exploring the underlying soundness of decision making and the capacity for flexibility in a crisis. Any future changes in the training and assessment of anaesthetists must be based on correct understanding of what we learn, how we use that knowledge and how best it can be assessed. Until the time that research is done, measurements made in the workplace should not be used either to monitor the progress of trainees or make decisions in relation to their careers.

CLINICAL INVESTIGATIONS

Pharmacokinetic and clinical study of ropivacaine and bupivacaine in women receiving extradural analgesia in labour

A. F. McCrae, P. Westerling and J. H. McClure

Summary

We have compared, in a randomized, double-blind study, the pharmacokinetics of ropivacaine and bupivacaine during labour. Total and free plasma concentrations of ropivacaine and bupivacaine were measured after the first of two extradural doses. The main dose was 20 mg (test dose) and 30 mg, with a top-up dose of 25 mg when requested. After the main dose, $C_p$max (total) of ropivacaine (0.50 mg litre^{-1}) was similar to that of bupivacaine (0.48 mg litre^{-1}). At 20 min, $C_p$max (free) of ropivacaine (0.04 mg litre^{-1}) was higher than that of bupivacaine (0.02 mg litre^{-1}) (P=0.0025). The clinical effectiveness of the block was similar in both groups. (*Br. J. Anaesth.* 1997; **79**: 558–562).

Key words
Pharmacokinetics, ropivacaine. Pharmacokinetics, bupivacaine. Anaesthetics local, bupivacaine. Anaesthetics local, ropivacaine. Analgesic techniques, extradural. Analgesia, obstetric.

Ropivacaine (S-(-)-1-propyl-2', 6'-pipecoloxylidide hydrochloride monohydrate) is a long-acting amide local anaesthetic. It is closely related structurally to bupivacaine, but unlike bupivacaine, which is a racemic mixture, ropivacaine is the single S-enantiomer. Ropivacaine has pharmacodynamic and pharmacokinetic properties resembling those of bupivacaine in animals and humans,[1–3] but has less central nervous system toxicity and cardiotoxicity than bupivacaine.[4 5]

Initial clinical studies of extradural anaesthesia with ropivacaine indicated overall pharmacodynamic and pharmacokinetic properties comparable with those of bupivacaine.[6] In double-blind studies comparing ropivacaine and bupivacaine, onset and duration of sensory block and overall clinical efficacy of anaesthesia were similar. Most studies have found that the depth and duration of motor block were less with ropivacaine than bupivacaine when used in equal concentrations.[7–9]

In an early study of bupivacaine in ewes, cardiotoxicity was enhanced by pregnancy.[10] However, subsequent work failed to find a difference in toxicity between pregnant and non-pregnant ewes after bupivacaine or ropivacaine.[11] Both ropivacaine and bupivacaine are weak bases and are bound to α_1-acid glycoprotein (AAG) in plasma. The unbound (free) drug concentration is considered to be related to systemic pharmacodynamic and toxic effects.[12] Studies of ropivacaine in pregnant and non-pregnant ewes showed that pregnancy was accompanied by altered pharmacokinetics; total clearance of ropivacaine was lower in pregnant compared with non-pregnant ewes.[13]

The principal aim of this study was to investigate free and total plasma concentrations of ropivacaine or bupivacaine after an extradural dose of 50 mg, given to pregnant women in labour. The secondary aim was to assess central neural block and the safety of ropivacaine and bupivacaine in extradural analgesia in labour.

Patients and methods

This randomized, double-blind study was approved by the local Ethics Committee. Written informed consent was obtained before the study from 22 women in established labour, having regular painful contractions, and requesting extradural analgesia for pain relief. No previous analgesia other than nitrous oxide had been used. All patients were ASA I, at >36 weeks' gestation, with a singleton fetus in vertex presentation. Patients were allocated randomly to one of two matched treatment groups to receive ropivacaine or bupivacaine. Patients with a history of allergy to amide local anaesthetics, pre-eclampsia or drug abuse were excluded.

An i.v. infusion of Ringer's lactate was commenced and patients received up to 250 ml of fluid. A 16-gauge cannula was inserted into a vein in the contralateral antecubital fossa for blood sampling. After infiltration of the skin with 1% lignocaine, a 16-gauge Tuohy needle was inserted at the L2–3 interspace in the right lateral or sitting position and the extradural space identified with loss of resistance using less than 4 ml of saline. An end-holed catheter was inserted 3 cm in a cephalad direction. With the patient in the right lateral position and after negative aspiration tests for blood or CSF, a test dose of

A. F. McCrae, MB, ChB, DRCOG, FFARCSI, J. H. McClure, BSc(Hons), MB, ChB, FRCA, Department of Anaesthetics, Royal Infirmary, Edinburgh EH3 9YW. P. Westerling, PhD, Astra Pain Control AB, S151-85 Sodertalje, Sweden. Accepted for publication: June 20, 1997.

20 mg (4 ml) of the study drug (0.5% bupivacaine or 0.5% ropivacaine from identically labelled coded ampoules identified only by number) was injected at a rate of 0.5 ml s^{-1}. Five minutes later, the patient was turned to the left lateral position and 30 mg (6 ml) of the same test solution were injected over 12 s. When additional analgesia was requested, a top-up injection of 25 mg (10 ml) of the test solution in a concentration of 0.25% was given, with the patient in the wedged supine position. When a second top-up was requested, the drug administration period was complete and the extradural was continued using bupivacaine or lignocaine as appropriate until delivery.

BLOOD SAMPLING

Samples of blood (5 ml) were obtained from the venous cannula for measurement of local anaesthetic concentrations immediately before drug administration, at time 0 (end of injection of main dose), at 10, 20 and 30 min, at 1 h (2 h if before topped up) and immediately before the top-up injection. At 20 min after the main injection, additional 5-ml samples were obtained for measurement of free drug concentrations and AAG. Samples were transferred from the syringe into heparinized test tubes. Plasma was separated by centrifugation for 10 min at 3000 rpm at room temperature within 2 h of collection, transferred to fresh tubes (Cryotube 5 ml, Nunc, Denmark) and stored in a freezer at −20 °C until analysis.

BIOANALYTICAL METHODS

Analysis was carried out at the Department of Bioanalysis, Astra Pain Control, Sweden. Total concentrations of ropivacaine and bupivacaine in plasma were measured using capillary gas chromatography with nitrogen sensitive detection after liquid–liquid extraction.[14] The limit of quantification (LOQ) was set at 0.010 mg $litre^{-1}$ and between-day precision for ropivacaine and bupivacaine during the study was 3–9% (relative SD, RSD) measured in the concentration range 0.02–2.00 mg $litre^{-1}$. Free concentrations of ropivacaine and bupivacaine in plasma were measured using coupled column liquid chromatography after ultrafiltration.[15] Ropivacaine and bupivacaine were detected by ultraviolet at 210 nm, and the LOQ was set at 0.003 mg $litre^{-1}$. Between-day precision during the study was 7% (RSD) for both ropivacaine and bupivacaine at a concentration of 0.030 mg $litre^{-1}$. Assay of AAG was performed using a radial immunodiffusion procedure with commercially prepared kits (NOR-Partigen, Behringwerkie, Marburg, Germany). LOQ was set at 2 μmol $litre^{-1}$ and between-day precision was greater than 9% (RSD).

CLINICAL EVALUATION

At 30 min after the main dose and top-up, assessments of the upper level of sensory block to pinprick were made using a short-bevelled 27-gauge dental needle (Monoject 401). Assessments of motor block were made using a modified Bromage scale: 0=no motor paralysis (full flexion of hip, knee and foot), 1=inability to raise extended leg (just able to move knee), 2=inability to flex knee (able to move foot only) and 3=inability to flex ankle joint (unable to move foot or knee). At the same times evaluation of the quality of analgesia was judged by the investigator as good, moderate or poor. Maternal heart rate and arterial pressure were measured before the extradural, at 5, 10, 15, 20 and 30 min after the main dose or top-up and at 30-min intervals during labour. Fetal heart rate was recorded continuously on a cardiotocograph during the study and values recorded at the same times as maternal cardiovascular variables. Hypotension was defined as a decrease in systolic arterial pressure to less than 90 mm Hg and bradycardia as a decrease in maternal heart rate to less than 50 beat min^{-1}.

The mode of delivery (spontaneous vertex, forceps, ventouse or Caesarean section) and Apgar scores of the newborn at 1 and 5 min were recorded. Mother and baby were visited daily during their hospital stay and adverse events were recorded. Patients were contacted by telephone 1–2 weeks after delivery for follow-up.

Individual free and total plasma concentrations of ropivacaine and bupivacaine were measured. Peak plasma concentrations (C_{p}max) and time to peak concentrations (tC_{p}max) were estimated. Differences in pharmacokinetic data were calculated using the Wilcoxon signed rank statistic. $P<0.05$ was considered statistically significant.

Results

Twenty-two patients were recruited. There were technical problems with two patients in the bupivacaine group (spoiled blood samples in one and failure to obtain all blood samples in the other) and these two patients were replaced. The results presented therefore are clinical data for 22 patients and pharmacokinetic data for 20 patients.

In the ropivacaine group, there were five primiparous and five multiparous women compared with eight and four, respectively, in the bupivacaine group. There were no differences in patient characteristics between the groups (table 1).

All patients received the main and top-up doses. The median time to first top-up was 111 min in the ropivacaine group and 126 min in the bupivacaine group.

PHARMACOKINETIC EVALUATION

Plasma concentrations of ropivacaine (fig. 1) and bupivacaine (fig. 2) up to the time of requesting the first (study drug) top-up are shown. All parturients received a top-up dose of the study drug.

After the main dose, mean $C_P$max (total) of ropivacaine was 0.50 mg litre^{-1} (95% Wilcoxon confidence intervals 0.42, 0.56 mg litre^{-1}) and mean $C_P$max (total) of bupivacaine was 0.48 (0.39, 0.56) mg litre^{-1}. Twenty minutes after the main dose, mean C_P (total) was the same in both groups (0.47 mg litre^{-1}), but the free concentration of ropivacaine (C_P (free)) was 0.04 (0.03, 0.05) mg litre^{-1}, significantly higher than that of bupivacaine (0.02 (0.02, 0.03) mg litre^{-1}) ($P=0.0025$) (table 2).

Protein binding of ropivacaine (mean 92%) was lower compared with bupivacaine binding (mean 96%). The concentration of AAG was similar in the two groups, ranging from 9 to 19 μmol litre^{-1}, but there was a higher free fraction of ropivacaine than bupivacaine (fig. 3).

CLINICAL EVALUATION

The following results are described for 10 patients in the ropivacaine group and 12 in the bupivacaine group.

Sensory and motor block

Maximum segmental spread of sensory block after the main dose was T6–11 in the ropivacaine group and T4–11 in the bupivacaine group. After the top-up, spread was T7–10 in the ropivacaine group and T4–11 in the bupivacaine group. Motor block in the ropivacaine group was grade 0 in four and grade 1 in six patients after the main dose and grade 0 in two, grade 1 in six and grade 2 in two after ropivacaine top-up. In the bupivacaine group, motor block was grade 0 in five, grade 1 in six and grade 2 in one after the main dose and grade 0 in five, grade 1 in five and grade 2 in two after bupivacaine top-up (table 3).

Table 3 Motor block (Bromage scale)

	Ropivacaine (n=10)		Bupivacaine (n=12)	
	Main dose	Top-up	Main dose	Top-up
Grade 0	4	2	5	5
Grade 1	6	6	6	5
Grade 2	0	2	1	2
Grade 3	0	0	0	0

Quality of analgesia

This was assessed by the investigator 30 min after the main dose and was considered good in nine of 10 patients in the ropivacaine group and in 10 of 12 in the bupivacaine group. After the top-up, analgesia was good in nine of 10 in the ropivacaine group and in nine of 12 patients in the bupivacaine group.

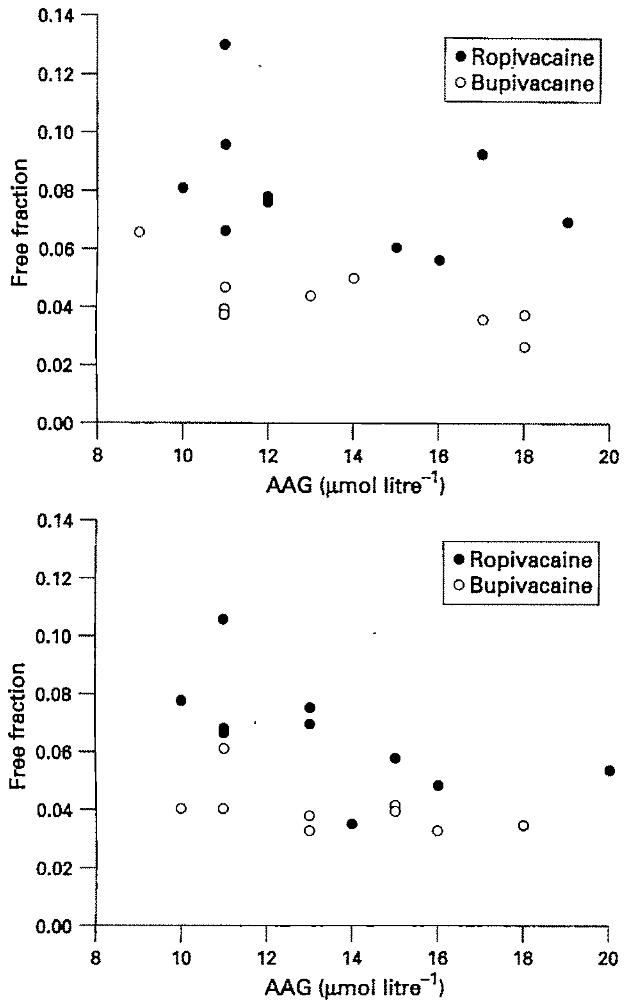

Figure 3 Free fraction of ropivacaine and bupivacaine *vs* plasma concentrations of α_1-acid glycoprotein (AAG) after the main dose.

Neonatal assessments

In the ropivacaine group, six patients delivered spontaneously, three required forceps and one patient had a Caesarean section for failure to progress. In the bupivacaine group, seven patients had spontaneous deliveries and five required forceps delivery. Apgar scores were >7 for all babies at 5 min.

Cardiovascular changes

There were no obvious differences between the groups in systolic or diastolic arterial pressures. In both groups there was a decrease in arterial pressure 10–20 min after the main dose and top-up. In each group, three patients became hypotensive. Two patients in the ropivacaine group were treated with ephedrine, but no patient in the bupivacaine group required ephedrine. There were two episodes of transient fetal bradycardia in each group, but no evidence of fetal distress.

Discussion

In this study, $C_p$max (total) after the main dose was similar for ropivacaine and bupivacaine. Other studies in animals[3] and patients[9 16] comparing extradural ropivacaine with bupivacaine have found higher $C_p$max (total) values for ropivacaine. This could be because of the higher lipid solubility and higher tissue protein binding of bupivacaine which binds to neural tissue and fat in the extradural space and therefore may have a lower rate of absorption. However, a study comparing the two drugs as extradural anaesthesia for Caesarean section[17] and a study in intercostal blocks[18] comparing the two agents found no difference in $C_p$max (total).

We found that the free concentration of ropivacaine (0.04 mg litre^{-1}) was greater than bupivacaine 20 min after the main dose (0.02 mg litre^{-1}). A higher free concentration of ropivacaine compared with bupivacaine was also found in studies of continuous extradural infusion in labour[16] and after a 150-mg extradural dose for Caesarean section.[17]

Basic drugs such as amide local anaesthetics are bound in plasma by AAG, which is an acute phase protein, and concentrations vary in disease states, trauma and after surgery. Protein binding of ropivacaine (92%) was less than bupivacaine (96%). It has been found that as the serum concentration of ropivacaine or bupivacaine increases, protein binding decreases.[11]

Plasma protein binding is not relevant to systemic toxicity when caused by accidental i.v. injection because the mass of plasma protein in the volume of blood exposed to the drug is overwhelmed, leaving a significant mass of unbound drug available for diffusion into the excitable tissue of the central nervous system and the heart.[19]

Local anaesthetic toxicity is related to free drug concentration.[12] It has been shown in sheep, using i.v. infusion of ropivacaine or bupivacaine, that there is no significant difference in the total serum concentration of each drug in pregnant and non-pregnant ewes at the onset of local anaesthetic toxicity. However, the dose of ropivacaine required to produce that serum concentration was 40–50% higher than the corresponding dose of bupivacaine. It was observed that in the pregnant sheep the free concentration of ropivacaine was greater than that of bupivacaine at the time of cardiovascular collapse.[11]

The higher free concentrations of ropivacaine compared with bupivacaine after extradural administration of similar doses during labour reflects the lower lipid solubility and binding of ropivacaine by plasma proteins. These observations were not accompanied by any adverse effects on the mother or fetus at the doses given in this study.

The total area under the plasma concentration *vs* time curve (AUC) and the apparent disposition half-life ($T_{1/2}$) could not be estimated because of too few sampling times and confounding factors such as additional top-ups, mostly with bupivacaine, and the different timings between extradural block and delivery.

Clinically, the effects of the two drugs were similar in terms of sensory and motor block during extradural analgesia in labour, as has been found in other studies.[20 21] There was no difference in the mode of delivery and no difference between the drugs in terms of motor block, as assessed by the

Bromage scale, at the doses given. The modified Bromage scale assesses both spread and intensity of motor block. It may not be sensitive enough to quantify differences in the intensity of motor block in the limited segmental spread in extradural analgesia in labour.

Magnetic resonance imaging of the extradural space of the thoracic spine

Y. HIRABAYASHI, K. SAITOH, H. FUKUDA, T. IGARASHI, R. SHIMIZU AND N. SEO

Summary

To clarify the anatomy of the extradural space of the thoracic spine, we have compared magnetic resonance (MR) images of the thoracic spine with those of the lumbar spine. In 20 healthy volunteers, T2-weighted axial MR images were obtained at the levels of the C7–T1, T7–8, T11–12 and L2–3 vertebrae. The posterior extradural space seen in the slice through the intervertebral disc varied in shape and size depending on the vertebral level, and the shape of the space converted from triangular to crescent-shaped on moving from the lumbar to the thoracic spine. In particular, the posterior extradural space was almost absent at the C7–T1 level, indicating that the posterior extradural fat was rudimentary or non-existent at the thoracocervical level. At this level, the dura mater seemed to be in direct contact with the ligamentum flavum. Segmentation of the posterior extradural space was commonly observed at the L2–3 and T11–12 levels; however, incomplete segmentation of the posterior extradural space was often present at the T7–8 level. (*Br. J. Anaesth.* 1997; **79**: 563–566).

Key words

Anatomy, extradural space. Measurement techniques, magnetic resonance imaging.

Understanding of the anatomy of the extradural space is the key to successful introduction of extradural catheters and medicines. Because extradural anaesthesia and analgesia is most frequently performed at the lumbar vertebral level, the anatomical study of the extradural space has been studied extensively at this level.[1-5] With respect to other vertebral levels, including the thoracic and cervical levels, however, few studies have been conducted.[6] The anatomical characteristics of the spine are significantly different between the thoracic and lumbar spine, and thus the anatomy of the extradural space may differ according to the vertebral level. Magnetic resonance (MR) imaging provides detailed information on the anatomy of the extradural space in living subjects.[1 7] To understand the anatomy of the extradural space at the thoracic vertebral level, we have compared MR images of the thoracic spine with those of the lumbar spine.

Subjects and methods

The Institutional Review Board approved our study, and informed consent was obtained from all subjects. We studied 20 healthy Japanese volunteers (14 men), aged 21–41 yr (median 28 yr). Mean weight, height and body mass index were 64 (range 47–85) kg, 167 (153–182) cm and 23 (19–28) kg m^{-2}, respectively. Subjects with lumbago or previous spinal surgery were excluded. MR imaging examinations were performed with the subject in the supine position. At the levels of the C7–T1, T7–8, T11–12 and L2–3 vertebrae, T2-weighted axial MR images were obtained using an MR imaging system (VISART/Progress, Toshiba Corporation, Tokyo, Japan) operating at 1.5 T. Technical specifications included a repetition time of 4000–5500 ms, echo time of 100 ms, slice thickness of 4 mm, number of slices 9–11 and a field of view of 20 cm. Measurements taken from the MR images included the area of the dural sac, sagittal and transverse diameters of the dural sac, anteroposterior dimension of the fat-filled posterior extradural space, and distance from the skin to the posterior extradural space. The area was measured using a digital planimeter (KP-90N, Uchida Yoko Ltd, Tokyo, Japan).

Data were analysed using ANOVA for differences among the four levels of the spine. If significant differences were observed, the Bonferroni test was used for *post hoc* analysis. Data for men and women were compared using the unpaired t test. $P<0.05$ was considered statistically significant.

Results

The axial slice through the intervertebral disc showed that the posterior extradural space was enclosed by the ligamentum flavum, articular capsule and the dura. The fat in the posterior extradural space, having a high signal and being uniform (white), appeared as a triangle, typically at

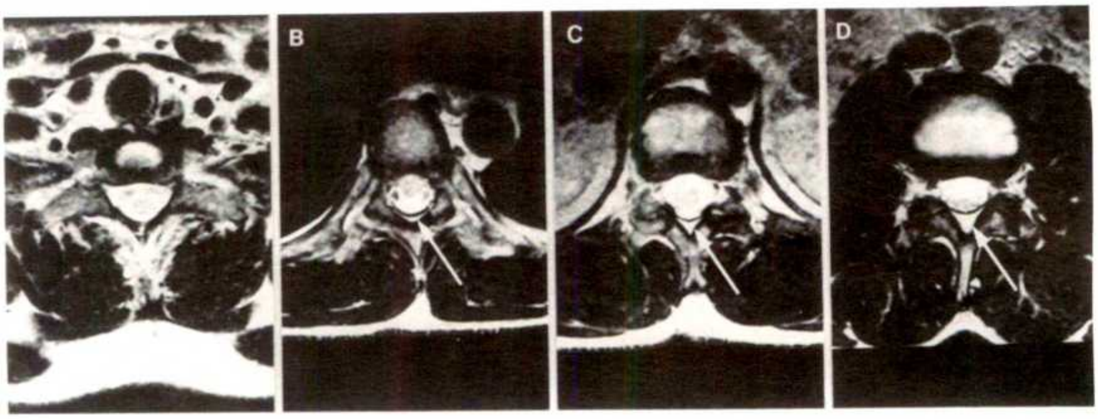

Figure 1 T2-weighted MR imagings showing the axial slice through the intervertebral disc at the C7–T1 (A), T7–8 (B), T11–12 (C) and L2–3 (D) levels. The arrows indicate the posterior extradural fat which has a high signal and is uniform. The shape of the fat converts from triangluar (C) to crescent-shaped (B) on moving from the lumbar to the thoracic spine. There is no posterior extradural fat at the thoracocervical junction (A).

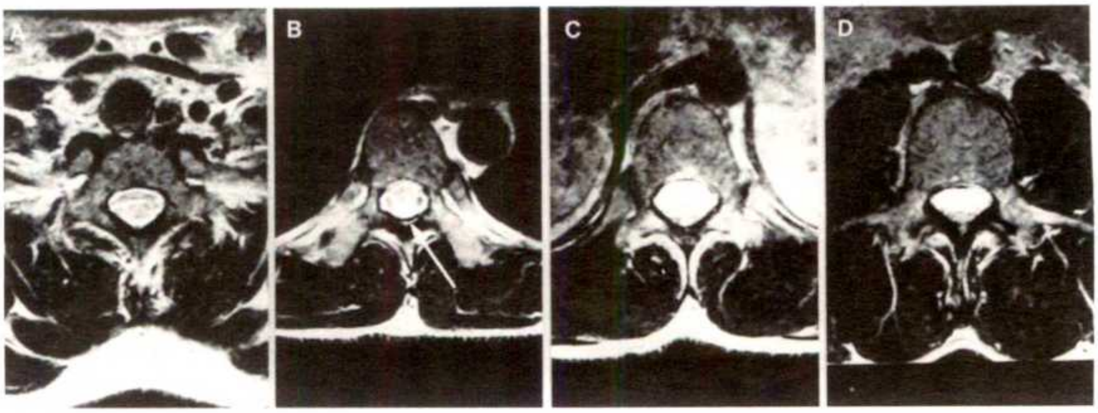

Figure 2 T2-weighted MR imagings showing the axial slice through the pedicles at the C7–T1 (A), T7–8 (B), T11–12 (C) and L2–3 (D) levels. The arrow shows the posterior extradural fat. The posterior extradural fat found only at the mid-thoracic level (B) indicates that the posterior extradural space at the mid-thoracic spine extends from one compartment to the next.

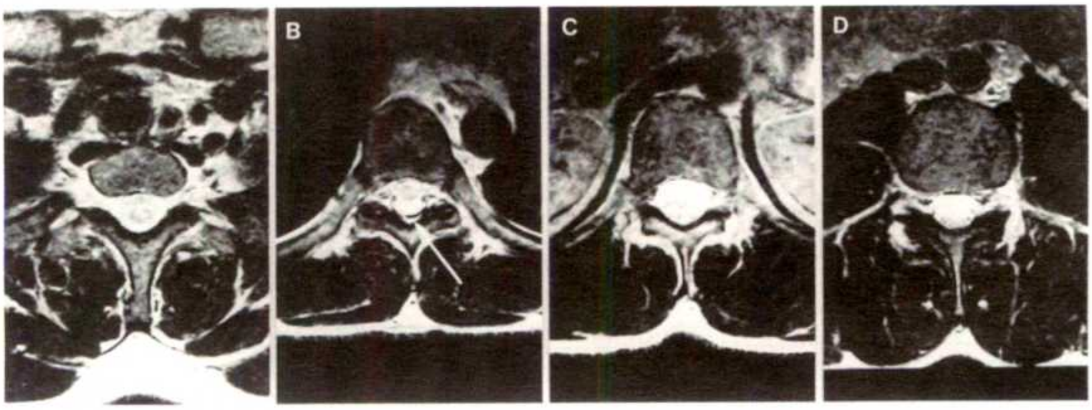

Figure 3 T2-weighted MR imagings showing the axial slice through the lamina at the C7–T1 (A), T7–8 (B), T11–12 (C) and L2–3 (D) levels. The arrow indicates the posterior extradural fat which lies between the dura and lamina at the level of the rostral lamina. The posterior extradural fat is found only at the mid-thoracic level (B).

the lumbar spine (fig. 1D). The fat-filled posterior extradural space varied in shape and size depending on the vertebral level. The shape of the space converted from triangular (fig. 1C) to crescent-shaped (fig. 1B) on moving from the lumbar to the thoracic spine. The anteroposterior dimension of the fat-filled posterior extradural space was shorter at the thoracic levels than at the lumbar level ($P<0.001$) (table 1). The fat-filled posterior extradural space appeared as a thin crescent at the T7–8 level in all subjects (fig. 1B); however, at C7–T1, the space was almost absent (fig. 1A), indicating that the posterior extradural fat was rudimentary or non-existent at the thoracocervical level.

In contrast with the axial slice through the intervertebral disc, as a rule no posterior extradural fat was evident in the axial slice through the pedicles (fig. 2) and lamina (fig. 3). This indicated that the

posterior extradural compartment was discontinuous, separated by areas of contact of the dura with the rostral lamina. At the level of the rostral lamina, no posterior extradural fat was present at T11–12 (fig. 2C, 3C) and L2–3 (fig. 2D, 3D), or at C7–T1 (fig. 2A, 3A) in any subject. With respect to T7–8, however, the posterior extradural fat was often identified even at the levels of the pedicles (fig. 2B) and lamina (fig. 3B), indicating that the fat in the posterior extradural space at the mid-thoracic spine extended from one compartment to the next between the dura and lamina.

Significant differences between men and women were noted only at the C7–T1 level for measurements of the dural sac (table 2). There were no differences between men and women for measurements at the other three levels of the spine. The distance from the skin to the extradural space was greater in men than in women in the low thoracic and lumbar regions ($P<0.05$).

Discussion

Increasing evidence indicates that the extradural space is divided into posterior, anterior and lateral compartments by areas where bone and ligament are in contact with dura,[3 8] although traditional teaching describes this space as a circumferential structure. These three compartments distribute segmentally around the dural sac. The posterior extradural space is the space into which the needle and catheter enters during extradural anaesthesia, and hence understanding of the anatomy of the posterior extradural space is the key to successful block.[9] The posterior extradural space contains chiefly fat which appears as a high signal on T2- weighted MR images. The fat within this space may follow the margin of the posterior extradural space. The findings of this study showed that the posterior extradural fat significantly varied in shape and size depending on the vertebral level. The shape of the posterior extradural fat changed from triangular to crescent-shaped on moving from the lumbar to the thoracic spine. At the thoracocervical junction, posterior extradural fat was almost absent. These findings may suggest that the effective capacity of the posterior extradural space reduces on passing from the lumbar to the thoracic level. The progressively diminishing posterior extradural fat in levels cephalad from the lumbar spine may, in part, explain the smaller anaesthetic dose requirements at the thoracic and cervical regions than in the lumbar region.

In the low-thoracic and lumbar vertebral level, the posterior extradural fat was present in the axial slice through the intervertebral disc but not in the axial slices through the pedicles and lamina, which may suggest that the posterior extradural compartment is discontinuous, separated by areas of contact of the dura with the rostral lamina. The mid-thoracic spine, however, often showed a continuous layer of posterior extradural fat which extended between the dura and lamina even at the level of the rostral lamina. This indicated that the fat in the posterior extradural space at the mid-thoracic spine extended from one compartment to the next between the dura and lamina. Incomplete segmentation of the posterior extradural compartment observed in our MR images was confirmed by the recent observations of Hogan who examined the cryomicrotome section of the spine from cadavers.[6] The author demonstrated that incomplete segmentation of the posterior extradural compartment frequently occurs at the mid- and upper thoracic levels. Incomplete segmentation of the posterior extradural space at thoracic levels may, in part, explain the fact that catheters are easily inserted for a far longer distance without kinking in the thoracic than in the lumbar region.[10]

Textbooks describe the anteroposterior dimension of the posterior extradural space in the lumbar region as 5–6 mm[11] or 4–6 mm.[12] Nickallis and Kokri reported that the mean value of the dimension in the lumbar region was 6.8 (SD 1.9) mm.[13] Bevacqua, Haars and Brand published a value of 6.9 (4) mm.[9] Our study showed that the value of the anteroposterior dimension of the posterior extradural space at the L2–3 interspace was 7.1 (1.3) mm, which does not differ significantly from those published previously. With respect to the thoracic region, however, few studies have been conducted on the size of the extradural space.[12] The values reported in our study are, to our knowledge, the first measurements by MR imaging. In a recent detailed study of cryomicrotome section of the thoracic spine, the anteroposterior dimension of the posterior extradural space was not measured.[6]

The diminished anteroposterior dimension of the posterior extradural space in the upper and mid-thoracic spine suggests an increased incidence of unintentional dural perforation during extradural puncture. However, Giebler, Scherer and Peters reported that unintentional dural perforation was observed significantly less in the mid- and upper thoracic regions in 4185 patients receiving thoracic extradural catheterization.[14] Tanaka and colleagues also reported significantly less unintentional dural perforations in the cranial vertebral regions compared with the lower thoracic and lumbar regions.[15] Thoracic extradural procedures are usually attempted by clinicians with considerably more experience whereas new trainees usually start with patients requiring the lumbar approach, and thus there may well be a learning curve. In addition, in the mid-thoracic region, the laminae overlap and angulation of the spinous processes is steep. Consequently, cephalad angulation of the needle is required during insertion. This cephalad angulation produces a longer oblique course across the extradural space and may compensate for the diminished anteroposterior dimension of the posterior extradural space.[6] This obligatory angle also makes the blunt back surface of the Tuohy needle face the dura.

This study was performed in subjects of Japanese origin. All of our volunteers were of relatively small stature and weight compared with European or North American subjects, and hence the results of this study can be applied directly only to subjects of the same race and within the same age, stature and weight range of those in this study. In addition, the number of volunteers examined in this study was so small that definitive conclusions on the differences between men and women cannot be reached.

Pharmacokinetic–pharmacodynamic modelling of the EEG effects of Ro 48-6791, a new short-acting benzodiazepine, in young and elderly subjects

J. DINGEMANSE, J. HÄUSSLER, W. HERING, H. IHMSEN, S. ALBRECHT, M. ZELL, H. SCHWILDEN AND J. SCHÜTTLER

Summary

The objectives of this study were to explore, by a modelling approach, in nine young (24–28 yr) and nine elderly (67–81 yr) male subjects, the pharmacokinetics and pharmacodynamics of Ro 48-6791, a new water soluble benzodiazepine. A microprocessor-controlled i.v. infusion pump generated linearly increasing arterial plasma concentrations until predetermined EEG and clinical end-points were attained. This concentration was maintained for 15 min and thereafter the infusion was discontinued. Haemodynamic and respiratory variables were monitored continuously. At full reorientation of the subject, a second infusion cycle was started under the same conditions to investigate the reproducibility of the concentration–effect relationship. The plasma concentration–time profiles of Ro 48-6791 were fitted accurately to an open three-compartment model. Plasma concentrations of Ro 48-6792, an N-dealkylated metabolite, accumulated during the course of the study. Pharmacokinetic variables of Ro 48-6791 were similar for both groups. The largest differences between young and elderly subjects, respectively, were found for clearance (mean 85 (SD 23) *vs* 71 (15) litre h^{-1}) and k_{12} (11 (7) *vs* 7 (3) h^{-1}). The concentration–median EEG frequency relationship was described with a sigmoid Emax model. Elderly subjects showed slightly increased drug sensitivity compared with young subjects (EC_{50} 72 (25) and 44 (15) μg $litre^{-1}$ in young and elderly subjects, respectively). The concentration–response data of the second infusion cycle deviated from the fitted curve suggesting either development of acute tolerance to the EEG effects of Ro 48-6791 or a role for drug metabolites. Because of the differences in sensitivity and clearance, lower doses of Ro 48-6791 should be administered to elderly compared with young subjects in order to achieve similar effects. (*Br. J. Anaesth.* 1997; **79**: 567–574).

Benzodiazepines are in widespread use as sedative–hypnotic agents.[1] Parenteral midazolam and other benzodiazepines are currently the most frequently used sedatives for conscious sedation.[2] Midazolam is also in widespread use for both induction and maintenance of general anaesthesia[3] and it is frequently administered for long-term sedation of critically ill patients in intensive care units.[4]

Midazolam is considered by many practitioners to be associated with a longer duration of action and greater inter-individual variability of effect than is desirable.[5 6] A sedative drug with the advantages of midazolam but with a shorter duration of action and less variability would be of great benefit.

Ro 48-6791 (3-(5-dipropylaminomethyl-1,2,4-oxadiazol-3-yl)-8-fluoro-5-methyl-5,6-dihydro-4H-imidazo [1,5-a]$^{1\,4}$ benzodiazepin-6-one) (fig. 1) is a new water soluble full agonist at the benzodiazepine receptor. In the first study in humans, in which doses of 0.1–3 mg were given i.v. over 20 min, Ro 48-6791 was shown to be well tolerated and to elicit dose-dependent central nervous system depressant effects.[7] An integrated pharmacokinetic–pharmacodynamic approach[8] applying neurophysiological effect measures (saccadic eye movements and electroencephalography β-power) provided pivotal data for further clinical development of Ro 48-6791. The compound had a comparable onset and duration of action to midazolam but was approximately five-fold more potent[7] and its volume of distribution and plasma clearance were larger than those of midazolam. The monopropyl metabolite Ro 48-6792 (fig. 1) rapidly appeared in plasma and seemed to have a longer elimination half-life than the parent compound.

The objectives of this study were to investigate in

both young and elderly subjects the pharmacokinetics and pharmacodynamics of Ro 48-6791 in a concentration range for potential use in anaesthesia rather than conscious sedation. Arterial blood samples were collected during and after linearly ascending blood concentrations to exploit the advantages of pharmacokinetic–pharmacodynamic modelling approaches.[9 10] After recovery from the effects of the first infusion cycle, the drug was again infused until the same predetermined pharmacodynamic end-point was reached. This strategy was designed to evaluate the potential contribution of the metabolite Ro 48-6792 to the overall drug effects.

Subjects and methods

We studied 18 male subjects, nine young (age 24–28 yr, weight 66–89 kg) and nine elderly (age 67–81 yr, weight 71–90 kg), regarded as healthy on the basis of medical history, physical–neurological examination, 12-lead ECG and clinical laboratory measurements. Subjects were non-smokers and absence of drug abuse (including benzodiazepines) was verified by urinary screening. Three elderly subjects were receiving antihypertensive drugs and one was also receiving treatment for chronic heart failure. All subjects gave written informed consent before any screening procedures were performed. The study was approved by the Medical Ethics Review Committee of the Medical Faculty of the University of Erlangen, Erlangen, Germany.

STUDY DESIGN

All 18 subjects received treatment with Ro 48-6791. For safety reasons, the young subjects were treated before the elderly subjects. Commonly, two subjects were treated on one day. Subjects fasted for at least 8 h before the start of administration of the study drug until full orientation after the second infusion cycle. To avoid hypoglycaemia, Ringer's solution with glucose was infused during the study. The drug was given i.v. with a microprocessor-controlled (Toshiba 1850 C) infusion pump (Braun Perfusor fm, Braun, Melsungen, Germany) yielding linearly increasing plasma concentrations. The infusion rate was programmed to generate an increase in plasma concentration of 180 and 90 μg litre^{-1} h^{-1} in the young and elderly subjects, respectively. The slope of the plasma concentration increase in the elderly was reduced for safety reasons and anticipated increased drug sensitivity.[11 12] Pharmacokinetic variables obtained in the entry-into-human study[7] were used to program the software (IVA-PUMP, version 3.5., Erlangen, Germany). The study drug was infused until the median electroencephalographic (EEG) frequency was less than 4 Hz and the subject ceased to respond to a standardized loud acoustic stimulus. The concentration at which the sedation criteria were fulfilled was maintained for another 15 min before the infusion was terminated. As soon as the subject was fully oriented with regard to person, place and time, a second infusion cycle was started under the same conditions and with the same assessments.

PROCEDURES AND ASSESSMENTS

After ulnar artery blood supply had been examined by the Allen test, a cannula (Arrow, 20-G) was inserted by the Seldinger technique under local anaesthesia (Scandicain 1%, Astra Chemicals) into the radial artery of the non-dominant arm. Another cannula (Viggo, 18-G) was inserted into a forearm vein of the contralateral side for infusion of drug and glucose solution. Haemodynamic and EEG monitoring devices were installed and after a rest of approximately 10 min, stable baseline values of arterial pressure, heart rate, oxygen saturation and EEG were recorded.

Safety and tolerability

Adverse events were assessed by spontaneous reports, observations and questioning at regular intervals. The intensity of the adverse event was rated on a three-point scale (mild, moderate, severe). Systolic, diastolic and mean arterial pressures, and heart rate were monitored continuously via an arterial cannula (Sirecust 1281, Siemens) and the ECG was monitored continuously (Sirecust 1281, Siemens). Oral body temperature was measured just before start of the first infusion cycle, once during each period of constant plasma concentration and at the time of full orientation after the second cycle. Respiratory function was monitored continuously by pulse oximetry. When oxygen saturation decreased to less than 93% and 87% in young and elderly subjects, respectively, oxygen was administered by mask at a flow rate of 3–4 litre min^{-1}. During the phases of constant plasma concentration, an arterial blood sample was analysed for blood-gas tensions (BMS SMK2, Radiometer Copenhagen). After termination of the study, a physical examination and routine clinical laboratory tests were performed again.

Analytics and pharmacokinetics

Blood samples of 2.5 ml were collected into Monovettes containing EDTA as anticoagulant via the indwelling arterial cannula. The dead space of the cannula (approximately 300 μl) was flushed with a small amount of physiological saline after each blood sample. Before obtaining each sample for analysis, 1 ml of blood was obtained and discarded. The two infusion cycles were divided into two periods, periods A and B, and periods C and D, respectively. Period A was the first infusion period (including the plateau phase) followed by period B, the first recovery period, terminated by complete reorientation of the volunteer. Periods C and D were the respective phases of the second infusion cycle. During periods A and C, blood samples were obtained every 3–5 min. During periods B and D, blood was collected at increasing intervals of 2–30 and 2–60 min, respectively. In general, blood samples were collected for up to 6 h after termination of the second infusion with a total blood loss of approximately 160 ml per subject. After centrifugation, plasma samples were stored at −20 °C until analysis.

After precipitation of plasma proteins with acetonitrile, Ro 48-6791 and its metabolite Ro 48-6792 were extracted simultaneously from the supernatant on a trapping column using on-line solid phase extraction and separated on an analytical column with column-switching liquid chromatography. The effluent from the analytical column was passed directly to an ion spray interface coupled to a tandem mass spectrometer (LC-MS/MS). Mass spectrometric detection of the analytes was performed using selected reaction monitoring. Mean precision (coefficient of variation) and accuracy (percentage of real concentration present) for Ro 48-6791 and Ro 48-6792 in the concentration range 1.0–50 μg litre^{-1} were 6.1% and 101.7%, and 6.9% and 99.7%, respectively. The lower limit of quantification for both Ro 48-6791 and Ro 48-6792 was 0.5 μg litre^{-1}, using a 0.1-ml aliquot of plasma. Pharmacokinetic variables were calculated using standard techniques[13] and fitted to an open three-compartment model using the program NONMEM.[14]

Pharmacodynamics

EEG recording began 10 min before administration of Ro 48-6791 and was continued until the early second recovery period when subjects had regained full orientation. The EEG was recorded using the CATEEM electrodiagnostic monitoring system (Computer Aided Topographical Electro-encephalometry, Medisyst, Linden, Germany). Bipolar cerebral activity was acquired using an electro-cap (Electro-Cap, Electro-Cap International, Eaton, OH, USA) with the electrodes positioned according to the international 10–20 system and using Cz as reference. The gap between the cavities of the electrodes and the tissue was bridged by an electrolytic jelly. The signals were preamplified with a battery-powered amplifier close to the head and the resulting digital code was transmitted by optical fibre to the CATEEM system. Artefact-free serial epochs of 4 s were digitized at a rate of 512 Hz (12 bit) using bandpass filters between 0.45 and 35 Hz. The high input impedance ensured a sufficient signal-to-noise ratio with electrode impedances ranging from 1 to 100 kΩ. An additional display of the unprocessed raw EEG was used to check the variables derived. For each lead, EEG analysis included changes within individual band power and median frequency, defined as the frequency which divides the area below the power spectrum curve into two equal parts. The individual frequency bands were set as follows: delta 1.25–4.5 Hz, theta 4.75–6.75 Hz, alpha$_1$ 7.0–9.5 Hz, alpha$_2$ 9.75–12.5 Hz, beta$_1$ 12.75–18.5 Hz and beta$_2$ 18.75–35.0 Hz. To correlate the EEG changes with plasma concentrations, the values of the central lead of the dominant hemisphere (C_3) were used from the 17 channels derived. As the CATEEM system excludes the subdelta band (0.5–1.25 Hz) from the power spectral analysis, the raw EEG signal of this lead was transferred to a separate PC-based analysis tool. There, the power spectrum was analysed from 0.5 to 32 Hz and median frequency calculated subsequently (EEG-BASIC, version 2.4, Bonn, Germany), thus receiving more information during the pronounced hypnotic effect. Median frequency was used as a pharmacodynamic effect measure for modelling purposes.

Pharmacokinetic–pharmacodynamic modelling

Visual inspection of individual plasma concentration–median EEG frequency curves showed that the relationship could most adequately be described by a sigmoid Emax model[15]:

$$\mathrm{E}=\mathrm{E}_0-\frac{\mathrm{Emax}\times C_P{}^{\gamma}}{\mathrm{EC}_{50}{}^{\gamma}+C_P{}^{\gamma}}$$

where E=median frequency (Hz); E_0=baseline median frequency (Hz); Emax=maximum possible effect on median frequency attributable to the drug (Hz); C_P=plasma concentration of Ro 48-6791 (μg litre^{-1}); EC_{50}=plasma concentration of Ro 48-6791 (μg litre^{-1}) that gives 50% of the maximum attainable inhibition in median frequency; and γ=Hill coefficient, a variable which describes the steepness of the concentration–response relationship (no dimension).

Pharmacokinetic–pharmacodynamic modelling procedures were performed by incorporating a hypothetical effect compartment. The rate of drug transfer out of the effect compartment was characterized by the rate constant k_{eq} (h^{-1}). The half-life of equilibration ($T_{1/2eq}$) was calculated by ln $2/k_{eq}$. The pharmacodynamic model variables were estimated for the first infusion cycle by non-linear regression analysis using NONMEM and the optimum-fit pharmacokinetic variables.

STATISTICAL ANALYSIS

Differences between young and elderly volunteers were tested for statistical significance by the unpaired Student's *t* test. $P<0.05$ was considered statistically significant.

Results

SAFETY AND TOLERABILITY

All 18 subjects completed the study according to the design, without any serious adverse events. Apart from central depressant activity, few adverse events were reported. One young subject reported a fever lasting for approximately 15 h, 1 day after treatment with Ro 48-6791. Mild atrial arrhythmia and excessive dreaming, for 5 min during the second infusion cycle and during the night after drug administration, respectively, were reported by two elderly subjects. In a few subjects oxygen saturation decreased to less than the threshold set, but normalized immediately after administration of oxygen by mask. All participants breathed spontaneously during the entire observation period. Systolic, diastolic and mean arterial pressures, and heart rate, remained stable during the study in all subjects. Body temperature transiently decreased slightly to less than 35 °C in two elderly subjects. There was no pattern of abnormal laboratory values during the study which suggested a treatment effect, and the abnormalities observed were judged to be clinically irrelevant. The investigations performed at the post-study screen did not reveal clinically relevant differences from the baseline situation.

PHARMACOKINETICS

Table 1 presents the duration of each infusion cycle, time interval between the two cycles and dose of Ro 48-6791 administered in each cycle. Figure 2 shows the plasma concentration–time courses of Ro 48-6791 and Ro 48-6792 in a representative elderly subject. The fitted curves, on the basis of a three-compartment model for Ro 48-6791 and a two-compartment model for Ro 48-6792, are also given. In the ascending part of the two infusion cycles the concentration of the parent drug increased linearly with time. After the predetermined pharmacodynamic end-point had been reached, relatively constant concentrations of Ro 48-6791 were maintained for 15 min in most subjects. The metabolite Ro 48-6792 appeared rapidly in plasma and surpassed concentrations of the parent drug shortly after termination of the first infusion.

Table 1 Dose and duration of infusion of Ro 48-6791 in the two infusion cycles (mean (SD))

	Young	Elderly
Period A–B		
Duration (min)	42 (3)	43 (5)
Dose (mg)	15.4 (2.6)	8.4 (1.8)
Period C–D		
Duration (min)	34 (3)	38 (3)
Dose (mg)	11.0 (1.7)	6.9 (1.2)
Interval between cycles (min)	45 (10)	48 (11)
Total dose (mg)	26.4 (3.2)	15.2 (1.9)

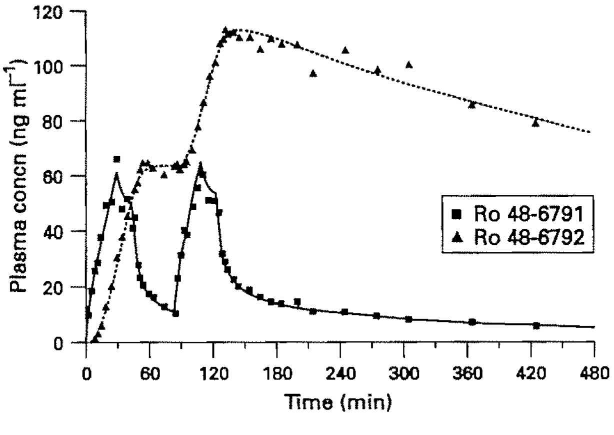

Figure 2 Actual and fitted plasma concentration–time course of Ro 48-6791 and Ro 48-6792 during and after both infusion cycles in a representative elderly subject (No. 101).

Table 2 Pharmacokinetic variables of Ro 48-6791 in young and elderly subjects analysed by an open three-compartment model (mean (SD))

	Young	Elderly
k_{12} (h^{-1})	11 (7)	7 (3)
k_{21} (h^{-1})	3.3 (1.3)	3.1 (0.9)
k_{13} (h^{-1})	3.3 (2.3)	3.8 (2.0)
k_{31} (h^{-1})	0.4 (0.3)	0.4 (0.1)
Cl_1 (litre h^{-1})	85 (23)	71 (15)
Cl_2 (litre h^{-1})	189 (47)	131 (33)
Cl_3 (litre h^{-1})	56 (22)	67 (29)
V_1 (litre)	20.5 (7.1)	19.5 (5.8)
V_2 (litre)	60.7 (14.8)	43.8 (13.0)
V_3 (litre)	152 (74)	162 (62)
V_{ss} (litre)	233 (80)	226 (57)
$T_{1/2}{}^{\alpha}$ (h)	0.041 (0.019)	0.046 (0.016)
$T_{1/2}{}^{\beta}$ (h)	0.56 (0.19)	0.49 (0.19)
$T_{1/2}{}^{\gamma}$ (h)	3.8 (1.4)	3.7 (0.8)

During the second infusion cycle, plasma concentrations of Ro 48-6792 accumulated further and by the end of the second infusion were much higher than those of Ro 48-6791. Thereafter, concentrations of Ro 48-6792 declined slowly in comparison with those of Ro 48-6791. In both groups, Ro 48-6791 showed a high plasma clearance, small initial volume of distribution and relatively short half-life (table 2).

PHARMACODYNAMICS

The time course of the changes in median EEG frequency during and after infusion of Ro 48-6791 in an elderly subject are shown in figure 3. Baseline median EEG frequency was approximately 7–9 Hz in all subjects. After the start of the first infusion, approximately 12 subjects initially showed a slight increase in median frequency. Relatively shortly before the pharmacodynamic end-point was reached, the effect variable decreased sharply to values close to 2 Hz. The time course of the return to baseline values in both recovery periods was steep. It

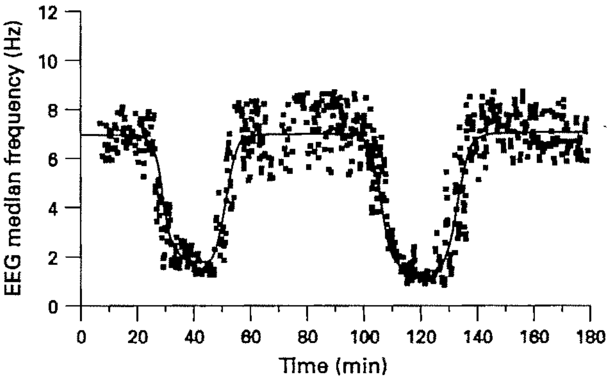

Figure 3 Median EEG frequency as a function of time during and after both infusion cycles in an elderly subject (No. 101).

appeared that during the second infusion cycle similar maximum drug effects occurred. Table 3 presents the pharmacodynamic variables estimated by fitting a sigmoid Emax function to the concentration–effect data of the first infusion cycle. Baseline values were slightly lower in the elderly than in the young subjects. Based on its EC_{50} values, Ro 48-6791 appeared to be a very potent benzodiazepine. Elderly subjects were more sensitive to the drug than young subjects. The concentration–effect relationship appeared to be steep, particularly in elderly subjects. Hysteresis between arterial plasma concentration and response was found in seven young and eight elderly subjects. Median k_{eq} values were similar in both groups. The equilibration half-life ($T_{1/2eq}$) was approximately 5–7 min. A representative plasma concentration–response plot during the first infusion cycle is given in figure 4 showing the hysteresis loop. Collapse of the hysteresis loop by incorporation of an effect compartment into the pharmacokinetic–pharmacodynamic model yields the effect compartment concentration–response plot of figure 5. In most subjects, the pharmacodynamic variable estimates of the first infusion cycle when applied to the second cycle led to less optimal characterization of the time course of effect in the latter (fig. 6).

Table 3 Pharmacodynamic variables of Ro 48-6791 in young and elderly subjects on the basis of a sigmoid Emax model and a hypothetical effect compartment. Values are means (SD) [median] of $n=9$. *$P<0.05$ compared with young subjects

	Young	Elderly

Discussion

This is the second study in humans of the new benzodiazepine Ro 48-6791 which was developed to induce conscious sedation and anaesthesia, with or without other agents.[3]

Ro 48-6791 showed a favourable tolerability profile in both young and elderly subjects. There were only minor changes in cardiovascular and respiratory variables. Previous studies have shown that in this respect differences between various benzodiazepines are minor, even between long- and short-acting compounds.[16] It should be realized that in our study, high concentrations of Ro 48-6791 were attained at the pharmacodynamic end-point comparable with approximately 1200 μg litre^{-1} of midazolam. These concentrations are anticipated to be higher than those expected during therapeutic administration of Ro 48-6791. Anaesthetic conditions are seldom created by administration of a benzodiazepine alone. Monotreatment with Ro 48-6791 was used in this study to obtain information on tolerance, pharmacokinetics and pharmacodynamics. Obviously, Ro 48-6791 should still be studied in patients with compromised ventilatory function but this study did not provide indications that its profile would differ from that of midazolam.

The pharmacokinetics of Ro 48-6791 were described most accurately by an open three-compartment model. In this study the pharmacokinetics were examined by high-resolution techniques, involving frequent arterial blood sampling. This enabled accurate delineation of the distribution and elimination phases. In both groups clearance was markedly higher than that of midazolam.[17] In elderly subjects clearance was only approximately 15% lower than in young subjects, whereas the distribution rate constant from the central to the shallow peripheral compartment (k_{12}) decreased by one-third. Little change in pharmacokinetics with age has also been reported with midazolam.[18 19] Both Ro 48-6791 and midazolam are metabolized oxidatively by isoenzymes of cytochrome P450. However, clearance of Ro 48-6791 is high and, therefore, more dependent on liver blood flow than on the oxidative capacity of the liver. The ratio of volume of distribution *vs* compartmental clearance with respect to the deep peripheral compartment (V_3/Cl_3) correlates inversely with the context-sensitive half-time after drug infusions that have not yet reached steady-state conditions.[20] The context-sensitive half-time is the time needed for a 50% reduction in drug concentration at the active site. This is because drug is still being taken up into the deep compartment thereby contributing to a reduction in concentration in plasma and the effect compartment. In contrast, a small Cl_3/Cl_1 ratio correlates with a shorter context-sensitive half-time after an infusion to steady state. This particularly reflects how rapidly drug leaves the deep compartment. With Ro 48-6791, V_3/Cl_3 and Cl_3/Cl_1 ratios were, on average, 17% larger and 40% smaller, respectively, than those for midazolam. A 30% faster recovery is usually considered as a change that is clinically discernible given the underlying variation in both pharmacokinetics and pharmacodynamics in a given patient.[20] These ratios indicate that, based on the pharmacokinetics of Ro 48-6791 *per se*, this drug might demonstrate a shorter duration of action than midazolam. The concentration–time courses in all subjects showed linearly ascending plasma concentrations during both infusion cycles providing evidence that the computer which controlled the infusion pump was programmed correctly, be it with two-compartment pharmacokinetic data. This study confirmed that Ro 48-6792 had a markedly longer elimination half-life than the parent compound. The sampling schedule did not allow accurate estimation of its half-life.

The pharmacodynamics of Ro 48-6791 were investigated using median EEG frequency as the effect measure. In contrast with drugs such as barbiturates and etomidate, infusion of benzodiazepines does not induce burst suppression. Therefore, a different pharmacodynamic end-point was chosen in this study. The EEG variable total number of waves between 12 and 30 Hz derived by aperiodic analysis has been used for pharmacokinetic–pharmacodynamic modelling studies with midazolam.[21] Bührer and colleagues derived the variable microvolts per second also from aperiodic analysis in the 0.5–30 Hz band.[22] Other authors have used the change in power determined by fast Fourier transform in the 12–30 Hz frequency band to investigate the pharmacodynamics of benzodiazepines.[23] Alternatively, the percentage change in alpha band activity (7.5–13.4 Hz) has also been used.[24] The difficulties inherent in the selection of a single univariate EEG variable to quantify the effects of benzodiazepines were illustrated by Fiset and colleagues[25] who used both aperiodic analysis and fast Fourier transform to describe the EEG effects of midazolam in a study in 10 subjects. In our study median EEG frequency was used as the effect measure as it is more reflective of the total effects of Ro 48-6791 on the EEG. Moreover, this variable has been used successfully in pharmacokinetic–pharmacodynamic modelling investigations with thiopentone, etomidate, propofol and eltanolone[26–28] and, therefore, has found wider use than variables based on aperiodic analysis. Median EEG frequency fulfilled virtually all prerequisites for an effect measure in kinetic–dynamic investigations.[29] Its clinical relevance needs to be demonstrated in studies which integrate several clinical end-points.

This study revealed a high potency for Ro 48-6791. The variability in EC_{50} was pronounced. This phenomenon has been described repeatedly for the pharmacodynamics of benzodiazepines.[6] Coefficients of variation of up to 50% have been reported by other research groups.[21 25 30] EC_{50} values in the range 180–384 μg litre^{-1} have been estimated for i.v. midazolam.[21 22 25] Mandema and colleagues reported a mean EC_{50} of only 77 μg litre^{-1}.[30] This illustrates on the one hand the marked variability in the pharmacodynamics of benzodiazepines or applied methodology, or both, and on the other hand the need to compare drugs or subject groups, or both, with the same strictly standardized method.[31] However, we can conclude that Ro 48-6791 is more potent than midazolam, in line with the findings of the first study in humans.[7] The potency of Ro 48-6791 was approximately 40% higher in elderly compared with young subjects. Increasing sensitivity of the central nervous system with age is often reported.[32] However, controlled clinical studies which take into account both pharmacokinetics and pharmacodynamics as sources of variations in drug response are rare. Greenblatt and colleagues described a linear concentration–effect relationship for triazolam in young and elderly individuals with no difference in intrinsic sensitivity between the two groups.[33] Another study reported increasing pharmacodynamic sensitivity to the hypnotic effects of midazolam in elderly subjects.[34] It is interesting to note that the influence of age on sensitivity appears to be more pronounced with inhalation anaesthetics than benzodiazepines.[35]

The difference in EC_{50} between young and elderly subjects in combination with the reduced clearance in elderly explain to a large extent the difference in total dose given to both groups to elicit the same pharmacodynamic end-point. Hysteresis in the plasma concentration–effect relationship was detected in most subjects. Median k_{eq} values in both groups were similar (8 and 6 h^{-1}). This implies a half-time of equilibration between plasma drug concentration and effect ($T_{1/2eq}$) of approximately 6 min. Values of 2–3 min have been reported in studies on midazolam with arterial blood sampling.[21 22] However, the EEG methodology in our study was different and, therefore, direct comparison between the two drugs is necessary. The established concentration–response relationships were steep, as reflected in the variable γ. In particular, the values obtained in elderly subjects were high. It remains to be investigated if midazolam shows the same phenomenon.

The pharmacodynamic variables estimated on the basis of the concentration–response data of the first infusion cycle poorly predicted the time course of effect during the second cycle. The second infusion appeared to induce the same decrease in median frequency but with a delayed onset. No major change was found in offset. There may be several explanations for this phenomenon. First, the influence of the metabolite Ro 48-6792 cannot be excluded. The more rapid cessation of drug effect would then suggest inverse agonistic activity of Ro 48-6792. However, various animal experiments investigating mixtures of Ro 48-6791 and Ro 48-6792 in different dose ratios did not provide support for this hypothesis (Jenck, personal communication, 1995). The first clinical study did not suggest pharmacodynamic effects of Ro 48-6792 but maximum plasma concentrations reached were only approximately 25 μg $litre^{-1}$. Alternatively, acute tolerance may develop to the high-dose EEG effects of Ro 48-6791 in the course of this study. The development of tolerance to benzodiazepines has been studied by Breimer[36] and Kroboth and Smith[37] who concluded that acute tolerance may occur. Other investigators did not obtain data indicative of acute tolerance development.[25 38]

Pharmacokinetics of midazolam given as an intranasal spray to adult surgical patients

S. BJÖRKMAN, G. RIGEMAR AND J. IDVALL

Summary

The aim of this study was to determine the bioavailability and absorption kinetics of midazolam given as an intranasal (i.n.) spray. In addition, plasma concentrations of the active metabolite, 1-hydroxymidazolam, were measured to give an indication of enteral absorption. An i.v. and i.n. midazolam dose were given in a crossover study to 14 adult surgical patients. Individual uptake profiles of i.n. midazolam were estimated by numerical deconvolution. After an i.n. dose of 0.15 mg kg^{-1}, maximum arterial plasma concentrations were 192 (SD 48) μg $litre^{-1}$ at 14 (2) min. Uptake of midazolam was rapid and bioavailability was 83 (15) %. Formation of the 1-hydroxy metabolite after i.n. administration did not exceed that after the i.v. dose. This demonstrates that under optimal conditions absorption of midazolam via the nasal mucosa was virtually complete. In this case little midazolam was swallowed and subjected to first-pass metabolism in the liver and therefore pharmacologically important amounts of active metabolite were not produced. Routinely administering i.n. midazolam under the assumption that the bioavailability is approximately 50% (as reported previously in the literature) may lead to overdosing in some patients. (*Br. J. Anaesth.* 1997; **79**: 575–580).

Key words
Hypnotics benzodiazepine, midazolam. Pharmacokinetics, midazolam.

Midazolam given by the intranasal (i.n.) route provides a more rapid onset of effect than that after oral or rectal administration.[1–3] Plasma concentrations of midazolam have been studied after i.n. administration to children.[2–6] Mean bioavailability was estimated at 55% when plasma concentrations after i.n. or i.v. administration were compared in two separate groups of six children each.[5]

I.n. midazolam has also been used in adult patients to produce anxiolysis and sedation. The technique has been described for endoscopic procedures and dental treatment,[7–9] and it might be particularly convenient for mentally retarded patients frightened of medical interventions such as venous cannulation.[10]

Absorption through the nasal mucosa circumvents first-pass metabolism in the liver. If a mean bioavailability of 55% is found, what is the fate of the remaining 45%? In the cited studies,[1–10] midazolam was administered as drops of aqueous solution which, unless expelled through the nostrils, are eventually swallowed. Some midazolam could therefore have been absorbed from the gastrointestinal tract. The mean bioavailability of oral midazolam in children has been estimated at 15–27%, depending on the dose.[11] This low bioavailability is chiefly the result of extensive first-pass metabolism producing 1-hydroxymidazolam as the main metabolite.[12–14] This metabolite is almost equipotent with midazolam as a CNS depressant.[14 15] Thus even if the mean bioavailability of unchanged midazolam after i.n. administration is only 55%, formation of active metabolite after intestinal absorption of the remaining dose could theoretically result in a total pharmacological effect approaching that after parenteral administration. Plasma concentrations of 1-hydroxymidazolam after i.n. administration of midazolam have not been measured.

The aim of this study was to determine the bioavailability of midazolam given as an i.n. spray. A complete crossover design allowing separate determination in each subject was possible in 14 adult surgical patients.

Patients and methods

After approval by the regional Ethics Committee and the Swedish Medical Products Agency, and after obtaining informed consent, we studied 14 patients (seven females and seven males), ASA I–II, undergoing elective breast or throat surgery. Mean age was 43 (range 28–55) yr, weight 79 (SD 12) kg and height 174 (10) cm. Patients receiving drugs with known metabolic interactions with midazolam and those with any liver dysfunction were excluded, as were patients with rhinitis or nasal obstruction.

All patients were premedicated orally with dixyrazine 25 mg. After an initial dose of fentanyl 0.1 mg, anaesthesia was induced with midazolam

0.15 mg/kg body weight given as an i.v. infusion of a 1 mg ml^{-1} solution (Dormicum, Roche AB, Sweden) over 2 min. Anaesthesia was maintained with intermittent i.v. injections of fentanyl (total dose during surgery 0–0.15 mg), and inhalation of isoflurane (end-tidal concentration 0.54–1.1%) and 70% nitrous oxide in oxygen. Neuromuscular block was produced with vecuronium and antagonized at the end of surgery with glycopyrronium–neostigmine. Mean duration of anaesthesia was 1.4 (range 0.8–3.0) h and of surgery 1.0 (range 0.6–2.5) h. In the recovery ward, where all patients stayed for 24 h, morphine was given for pain relief. In the evening, patients were given i.n. midazolam 0.15 mg/kg body weight. The drug was administered as a standard injectable solution (Dormicum) of 5 mg ml^{-1} with a spray bottle, with repeated sprayings alternating between nostrils. The spray bottle delivered a fine aerosol and the mean volume per activation was 0.09 (range 0.07–0.11) ml.

Monitoring during surgery and in the recovery ward included indirect arterial pressure, heart rate and arterial oxygen saturation (Sp_{O_2}) by pulse oximetry. Blood samples for drug assays were obtained from an arterial cannula inserted before induction of anaesthesia and kept patent with the aid of a continuous saline infusion (3 ml h^{-1}). Sampling was performed before and at 2, 4, 6, 9, 12, 15, 20 and 30 min and 1, 1.5, 2, 3, 4, 6, 8 and 10 h after the start of the i.v. infusion. Another sample was obtained before i.n. administration, 2–3.8 h later. Blood sampling was at 2, 4, 6, 9, 12, 15, 20, 30 min and 1, 1.5, 2, 3, 4, 6, 8 and 10 h. In the first five patients, blood sampling started after completion of spraying. As this was found to take several minutes, sampling in the remaining patients was scheduled from the beginning of administration and time to completion was noted. Consequently, the total time of each study was 22–24 h, and any deviation from the scheduled sampling time was noted and the true time used in data processing. Total blood sampling volume was 260 ml. Mean peroperative blood loss was 160 (range 25–350) ml.

Blood samples were kept on ice for a maximum of 2 h until centrifuged. Plasma was stored at −20 °C until assay within 8–12 weeks. The syringes and spray bottles were weighed before and after administration of their contents, and samples of the solutions were saved for assay.

Plasma samples were assayed for midazolam by gas–liquid chromatography (GLC) with electron capture detection[16 17] after addition of diazepam as internal standard and extraction with diethyl ether. The within-day coefficient of variation (cv) was 4.6% at 7.5 μg $litre^{-1}$ (3 ng $sample^{-1}$), 3.0% at 75 μg $litre^{-1}$ and 3.1% at 750 μg $litre^{-1}$ ($n=8$). The limit of detection was approximately 1 μg $litre^{-1}$, and the between-day cv was 11% at 60 μg $litre^{-1}$ ($n=8$). For each patient, samples from i.v. and i.n. administrations were assayed on the same day.

Plasma samples from eight patients were also assayed for 1-hydroxymidazolam by high pressure liquid chromatography (HPLC).[18] The within-day cv was 11% at 4 μg $litre^{-1}$ and 3.1% at 10 μg $litre^{-1}$, and the limit of detection was approximately 2 μg $litre^{-1}$.

Concentrations of midazolam in the i.v. and i.n. solutions were determined by HPLC[18] using the same standards as for the plasma assay, and each actual dose was calculated from the weight of administered solution and its measured concentration of midazolam.[19] Conventional compartmental models with elimination from the central compartment were fitted to the plasma concentration data from the i.v. administration, using PCNONLIN software (Scientific Consulting Inc., Apex, NC, USA). The final choice of model and weighting was three compartments and $concentration^{-1}$. The set of variables obtained included clearance (Cl), volume of distribution at steady state (V^{ss}), mean residence time (MRT) and terminal half-life ($T_{1/2}{}^{\gamma}$).

The contribution from the i.v. injection to the plasma concentration of midazolam after i.n. administration was subtracted from all measured concentrations, as shown in figure 1. The area under the concentration curves after i.v. and i.n. administration ($AUC_{i.v.}$ and $AUC_{i.n.}$) were calculated by the logarithmic trapezoidal method.[20] In both cases, extrapolation to infinite time was based on the terminal hybrid rate constant obtained from the PCNONLIN fit to the i.v. data. The bioavailability based on the AUC (F_{AUC}) of i.n. midazolam was then calculated using the standard formula:

$$F_{AUC}=\frac{AUC_{i.n.}\times dose_{i.v.}}{AUC_{i.v.}\times dose_{i.n.}} \qquad (1)$$

The absorption profile of i.n. midazolam was estimated by numerical deconvolution (fig. 2).[21] The PCNONLIN fit provided the theoretical disposition function of midazolam after instantaneous injection (as opposed to actual 2-min infusions), calculated by analytical deconvolution.[22] This equation was divided by the dose (in μg) to give the unit disposition function (UDF), that is the triexponential function that would describe the plasma concentration curve of midazolam after instantaneous injection of one dose unit (here, 1 μg). Numerical deconvolution

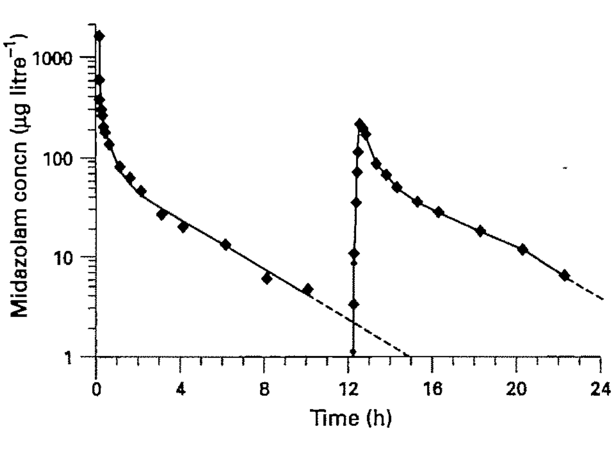

Figure 1 Arterial plasma concentration curves of midazolam in one patient during the study. A three-compartment model was fitted to the 0–10 h data after i.v. infusion. The symbols on the concentration curve after i.n. administration are concentrations after subtraction of the contribution from the i.v. infusion (in this case 1.9% of the total AUC after i.n. administration). After the first three data points, this difference is no longer visible. Broken lines=extrapolations based on the three-compartment fit. The extrapolated fraction of the AUC after i.n. administration was 5.9%.

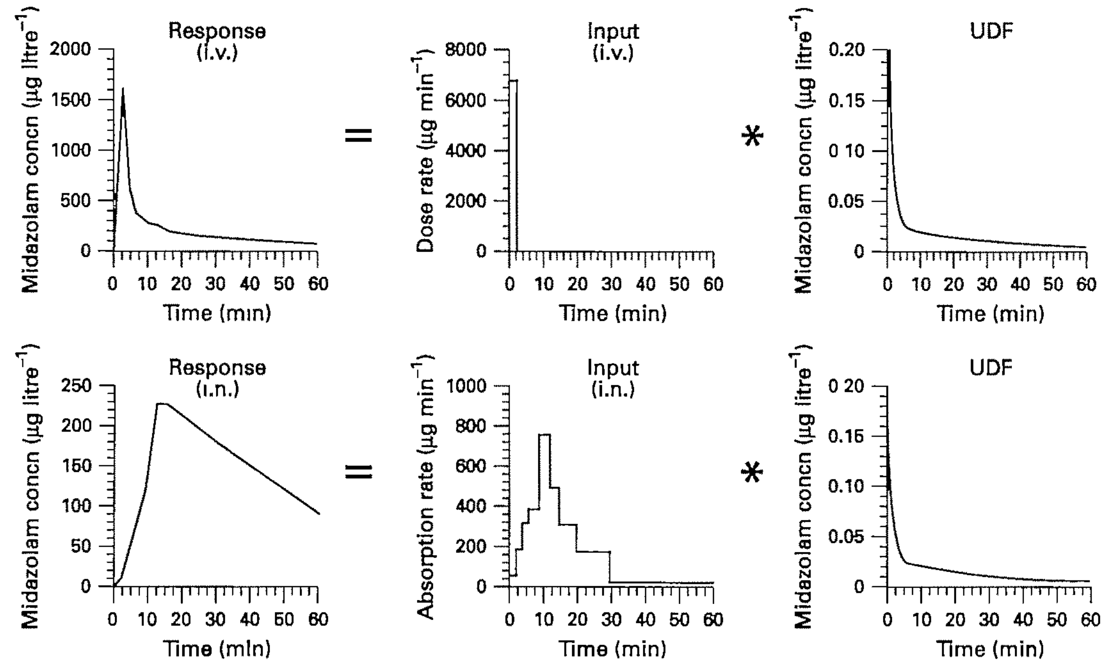

Figure 2 The principle of the deconvolution procedure. The asterisk denotes combination of two functions (curves) by the mathematical process of convolution. Top: observed pharmacokinetic response (i.e. plasma concentration curve) results from the input function of the drug (i.e. rate and duration of infusion) and the unit disposition function (UDF, i.e. the pharmacokinetics of the drug after instantaneous introduction of one dose unit, here 1 µg, into the circulation). The response is measured, the input is known and UDF can be calculated by deconvolution. Bottom: response (i.e. plasma concentration curve) is different from above as the input function has changed from a 2-min infusion to absorption with variable rate. As the response is measured and the UDF is known (and assumed to be unchanged) from the i.v. experiment, the input function can be estimated by deconvolution. Data are from the same patient as in figure 1.

of the i.n. plasma concentration curve and the UDF yielded the input function, which is the absorption profile of the drug. The input function was computationally constrained to be positive. The software was provided by Dr Davide Verotta, University of California at San Francisco, USA.

Integration of the input function gives the total absorbed amount of midazolam as a function of time. Bioavailability based on input (F_{inp}) was therefore calculated as:

$$F_{\text{inp}} = \frac{I_{\text{cum}}}{\text{dose}_{\text{i.n}}} \qquad (2)$$

where I_{cum}=cumulated input, that is absorbed midazolam at 10 h after dosing. This gives a cross-validation of the results.

The Student's *t* test was used to evaluate the statistical significance of the differences between the bioavailability of midazolam and 100% (unpaired test) and of drug-induced changes in arterial pressure (paired test). The level of significance was set at $P<0.05$ in one-tailed tests.

Results

The plasma concentration curves of midazolam for all patients are shown in figure 3 and the main pharmacokinetic variables in table 1. The absorption profiles of midazolam after i.n. administration are shown in figure 4. Bioavailability was generally high, with an excellent correlation (r^2=0.965) between F_{AUC} and F_{inp}. Mean values of F_{AUC} and F_{inp} were, however, both significantly different from 100%.

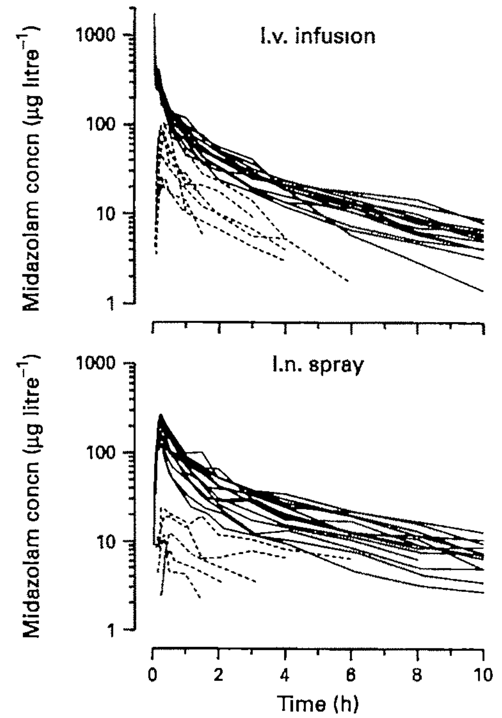

Figure 3 Individual arterial plasma concentration curves of midazolam (continuous) in 14 patients after i.v. and i.n. administration. Contributions from the i.v. infusion to the plasma concentrations after i.n. administration have been subtracted. These ranged from 0.3 to 6.3 µg litre^{-1} at 0 min and from <0.05 to 1.6 µg litre^{-1} at the end. The metabolite, 1-hydroxymidazolam (broken curves) was assayed in eight patients but was not detected reliably after i.n. administration in three.

Table 1 Main pharmacokinetic variables of midazolam after i.v. and i.n. administration to 14 surgical patients. The estimated tC_pmax is after the start of i.n. administration. Patient No. 4 was an outlier with a poorly estimated $T_{1/2}{}^{\gamma}$, and the values in parentheses are not included in mean (SD). For patient Nos 6–14, F_{AUC} was 87 (15) %

Uptake from the nasal mucosa was rapid and close to completion within 1–2 h (fig. 4). Dose-normalized AUC after i.n. administration varied 2.2-fold, from 1.13 to 2.47 min litre^{-1}, compared with 1.5-fold (1.62–2.41 min litre^{-1}) after i.v. infusion. The contribution from i.v. infusion to the total AUC after i.n. administration was 3.7 (2.7) %, and the error caused by subtraction would be a fraction of this percentage.

The concentration curves of 1-hydroxymidazolam in eight of the patients are included in figure 3. After i.v. infusion of midazolam, the $C_p$max of the metabolite was 28–104 μg litre^{-1} at 12–20 min. After i.n. administration of midazolam, $C_p$max for 1-hydroxymidazolam ranged from undetectable to 24 μg litre^{-1} at 15–26 min after the beginning of administration.

The i.v. dose of midazolam induced hypnosis in all patients within 4 min. Cardiovascular variables were stable with an initial mean arterial pressure (MAP) of 105 (11) mm Hg and with a maximum reduction (ns) to 96 (10) mm Hg within 15 min of induction of

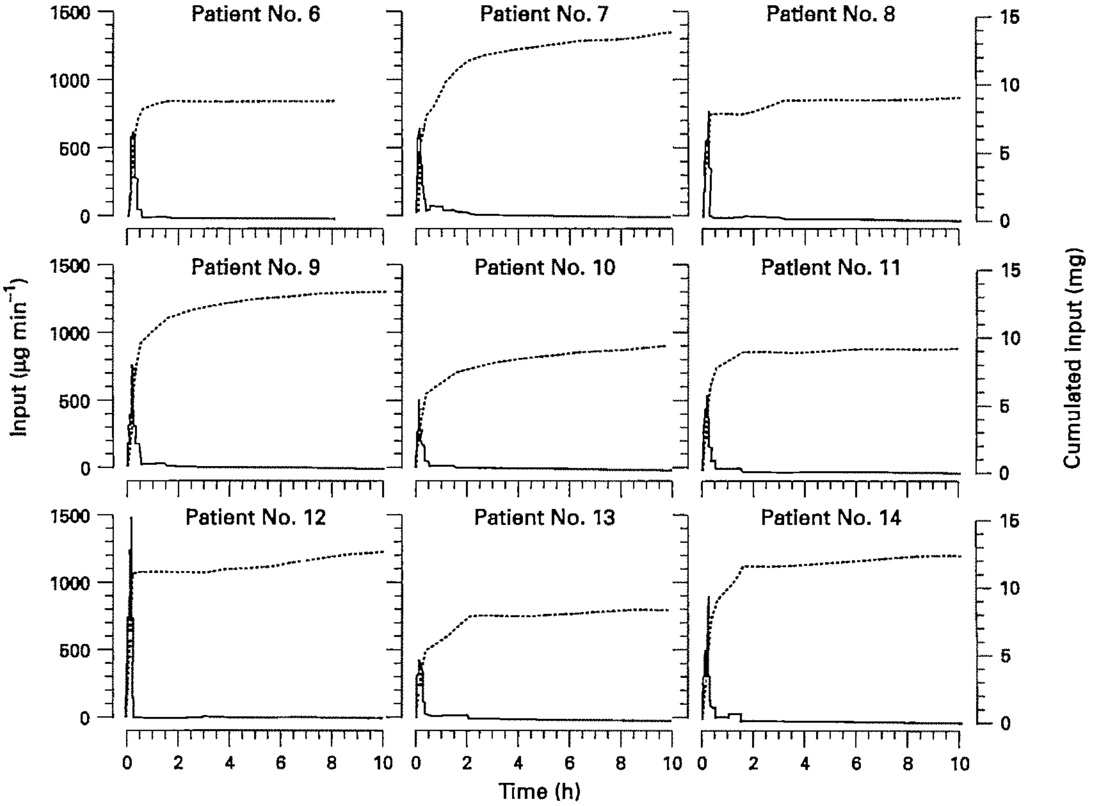

Figure 4 The input function, that is absorption of midazolam from the nasal mucosa (μg min^{-1}) during each blood sampling interval, and cumulated input (broken curve), that is total amount absorbed over time, in nine patients, with blood sampling from the beginning of i.n. administration. This took an average of 10 (range 8–13) min.

anaesthesia. The same dose administered i.n. had a less profound effect and a slower onset. After 6–14 min, that is a few minutes before mean tC_Pmax, all patients fell asleep but were rousable. Some patients found the solution slightly irritating or tickling, but all found the procedure acceptable. Cardiovascular variables were stable, MAP decreasing from 108 (12) to 105 (9) mm Hg (ns) when patients fell asleep. During anaesthesia Sp_{O_2} remained greater than 95% in all patients, but after i.n. midazolam administration desaturations occurred in five patients necessitating extra oxygen (5 litre min^{-1} by face mask) to achieve Sp_{O_2} >95%.

Discussion

This study had demonstrated that under optimal conditions absorption of midazolam via the nasal mucosa can be rapid and virtually complete. Routinely using an i.n. dose of midazolam that is twice the i.v. dose under the assumption that bioavailability is approximately 50% may lead to overdosing in some patients. The earlier study in childen[5] was not a crossover study and calculation of the rate of uptake of midazolam from the nasal mucosa was not attempted. In addition, administration of midazolam as i.n. drops may cause loss of solution either as sneezing,[1 3] spilling[4] or swallowing, all of which result in underestimation of bioavailability. As midazolam is not available in solutions higher than 5 mg ml^{-1}, large volumes must be given (at least 2 ml in normal adults).[7–10] Some of this solution is probably swallowed. We minimized spilling and swallowing by slow and careful spraying of approximately 0.1-ml aliquots. This proved time-consuming. However, in a 15-kg child three sprayings in each nostril would be sufficient to give a recommended[1 3] 0.2 mg kg^{-1} dose of midazolam.

The bioavailability of i.n. midazolam given by spray was greater than after oral administration in adults, with reported mean values in various groups of subjects of 46–68% (depending on dose),[12] 44%[23] or 36–50%.[24] As very little i.n. midazolam was apparently absorbed by the gastrointestinal route, the formation of 1-hydroxymidazolam did not exceed that after a parenteral dose of midazolam.

The deconvolution analysis revealed rapid uptake of midazolam, presumably chiefly from the nasal mucosa, in most patients. A more prolonged uptake, as in patient Nos 7, 10 and 13 (fig. 4), could to some extent be by gastrointestinal absorption. The tC_Pmax of midazolam was, however, highly reproducible at 14 (range 10–16) min after the beginning of spraying, and $C_P$max reasonably so at 192 (range 124–267) µg litre^{-1}. Similar mean tC_Pmax values of 13 min,[2] 10 min,[4] 12 min[5] or 12–16 min (with different doses)[6] were found after rapid instillation of i.n. midazolam solution in children. This suggests that absorption from the nasal mucosa is rate limiting and the time taken to administer the spray is relatively unimportant. Inter-individual variation in $C_P$max was similar[5] or tended to be greater[2 4 6] in the earlier studies compared with ours.

Midazolam was used as an i.v. induction agent before surgery and then as a hypnotic in the evening. Thus a crossover design was achieved with valid medical indications for both doses. This implied however that the i.v. dose was invariably given in the morning and the i.n. dose in the evening. As there is no apparent circadian variation in the clearance of midazolam,[25] we feel that this design was justified. We also avoided major (intra-abdominal) surgery which may influence the pharmacokinetics of midazolam.[26–28] Minor surgery[27] or administration of volatile anaesthetics[29] have not been found to significantly affect the disposition of midazolam. Putative interactions of anaesthesia, other medications and surgery would tend to lower clearance, that is increase the AUC_{iv} of midazolam. As the AUC_{iv} is in the denominator in equation (1), this would cause underestimation of F_{AUC} (and influence F_{inp} in a similar manner). The "true" F values would in this case be higher than we calculated.

The pharmacokinetic variables of midazolam after i.v. administration were also in good agreement with earlier findings in young to middle-aged healthy volunteers or patients undergoing minor surgery.[12 14 24 26 27 30–34] In studies using 12–24 h blood sampling, the mean terminal $T_{1/2}$ of midazolam was normally estimated at 2.1–3.3 h.[12 24 26 27 31–33] In approximately 6% of the population a considerably longer terminal $T_{1/2}$ was found,[27 33] and in our study this occurred in one of 14 subjects.

The observation that all patients were asleep but rousable a few minutes before a $C_P$max of 192 (48) µg litre^{-1} was reached is in good agreement with previous findings[30] at midazolam plasma concentrations of 150–200 µg litre^{-1}. In a later study in volunteers[34] a midazolam concentration of 131 (14) µg litre^{-1} at awakening was observed. In all studies, however, effects were recorded during non-steady state conditions, ignoring any effect of hysteresis[14] of midazolam. All patients had stable haemodynamic variables and minor oxygen desaturation was seen in only five patients, which is in good agreement with earlier findings on i.n. midazolam.[1 2 6 8 9]

In conclusion, this study has shown that the bioavailability of midazolam administered via the nasal mucosa was high and that active metabolite was not formed in pharmacologically important amounts. However, to achieve this, it is important to optimize nasal delivery by slow and careful spraying of the drug solution to avoid losses or swallowing. A good technique for doing this also in small children should be developed in order to fully exploit the advantageous pharmacokinetic and pharmacodynamic properties of midazolam.

Acknowledgements

We thank Ms Åsa Fyge and Mrs Bodil Roth for performing the assays of midazolam and its metabolite and Ms Christina Bengtsson for editorial assistance. The study was supported by Roche AB, Stockholm.

Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part I: elimination from the head

G. G. LOCKWOOD, D. P. DOB, D. J. BRYANT, J. A. WILSON, J. SARGENTONI,
S. M. SAPSED-BYRNE, D. N. F. HARRIS AND D. K. MENON

Summary

We describe the first human experiments to demonstrate wash-out of isoflurane using fluorine magnetic resonance spectroscopy. Using a surface receive coil, we found two-compartment kinetics within the head with decay half-times of 9.5 and 130 min, but the signal was too weak to localize the compartments. If the fast compartment is assumed to be the brain then our results match the predictions of the classical perfusion-limited pharmacokinetic model of inhalation anaesthesia. (*Br. J. Anaesth.* 1997; **79**: 581–585).

Key words
Anaesthetics volatile, isoflurane. Pharmacokinetics, isoflurane. Measurement techniques, magnetic resonance spectroscopy.

In the classical pharmacokinetic theory of inhalation anaesthesia, an inhaled anaesthetic is considered as an inert gas, the partial pressure of which slowly equilibrates throughout the body.[1] The partial pressure in each tissue approaches arterial partial pressure exponentially with a rate constant proportional to the perfusion of that tissue and to the ratio of blood solubility to tissue solubility for that anaesthetic. Inter-tissue diffusion and specific tissue binding are not usually considered. Published values of brain perfusion[2 3] and isoflurane solubility[4] predict a half-time for the equilibration between arterial blood and brain of 2–3 min. There are no specific binding sites of quantitative significance in the brain,[5] and no evidence of chemical bonding to body tissues,[6 7] so wash-out kinetics should match wash-in. The overall elimination of isoflurane from the brain at the end of an anaesthetic is slower than this because the concentration in arterial blood declines gradually (clearance by the lungs is imperfect), and the longer the anaesthetic, the slower the elimination from the brain as a greater drug load must also be cleared from the remainder of the body. One model of this process[8] predicts an elimination half-time of 7 min after 30 min of anaesthesia.

Fluorine magnetic resonance spectroscopy (^{19}F MRS) allows pharmacokinetic investigation *in vivo* because all modern inhalation anaesthetics are fluorinated. The first animal MRS experiments with halothane demonstrated very slow elimination of halothane from the brain, incompatible with the classical model.[9] Some of that MRS signal probably arose from fluorinated metabolites, and there has been debate over the identity of the tissue source of the signal.[10 11] Later animal studies demonstrated fast and slow compartments within the head (usually assumed to be brain and extra-cerebral tissue, respectively), but even in recent studies of isoflurane, estimates of the faster half-time have been greater than predicted by theory (36 min,[12] 25 min[13]) with only one exception (8 min[14]). A persistent problem with these studies is that the ^{19}F signal is too weak to allow dynamic imaging, and the location of the signal source has been estimated indirectly.

The question of delayed cerebral elimination of anaesthetics has obvious implications both for the recovery of "street fitness" in patients after anaesthesia and the validity of the standard perfusion-limited model of anaesthetic distribution. We have investigated this problem by undertaking the first ^{19}F MRS studies of isoflurane kinetics in humans. In this part of the study we have examined elimination of isoflurane from the head; in part II[15] the data are re-examined to estimate the rate of equilibration between end-expired gas and brain.

Subjects and methods

We studied healthy volunteers, aged 30–41 yr. Subjects gave written informed consent and the study was approved by the Medical Research Ethics Committee of Hammersmith Hospital and the Royal Postgraduate Medical School. Subjects lay in the left lateral position in the bore of the spectrometer and breathed oxygen via a Mapleson A system incorporating a non-ferromagnetic valve venting outside the magnet bore to eliminate trace concentrations of isoflurane in the air around the subject's head. The nares were occluded and subjects breathed through a

MENON, MB, BS, FRCA, MRCP, PHD, Department of Anaesthesia, Addenbrooke's Hospital, Cambridge Accepted for publication: June 13, 1997.

snorkel-style mouthpiece. There was no ^{19}F MR signal from the apparatus used. Pulse oximeter and ECG leads were passed through low pass filters to shield the spectrometer from radio frequency interference. End-tidal carbon dioxide and isoflurane concentrations were measured throughout using an infrared monitor (Capnomac, Datex, Finland) sampling via a catheter 6 m long. The monitor was calibrated before each experiment using QuickCal Standard (Datex, Finland). Digital output from the Capnomac was logged onto a computer and the analogue output of the volatile anaesthetic channel was recorded on paper. Subjects were attended by two anaesthetists: one remained outside the spectrometer's radio frequency screening enclosure watching the electronic monitors, the other was inside the enclosure monitoring respiration. Baseline measurements were made, and then a constant concentration of isoflurane (0.6% or 1%) was introduced into the inspired gas.

The spectrometer was a prototype Picker system operating at 1.5 T corresponding to a frequency of 64 MHz for fluorine and 60 MHz for protons. The transmitter coil was of saddle shape geometry, 52 cm in diameter, and could be tuned independently to both required operating frequencies. Radio frequency pulses of 200 ms could be generated for both ^{1}H and ^{19}F components of the study with this transmitter system and had sufficient bandwidth to excite equally all resonances of the ^{19}F spectrum. A 6 cm coil, also tuneable to both 64 and 60 MHz, was positioned over the subject's occipital region. This combination of coils gave a homogeneous transmit pulse over the whole head of the subject together with the improved sensitivity of a closely coupled receiver coil. The system was shimmed using the proton signal before acquisition of the ^{19}F spectra. The radio frequency pulse was calibrated by an external non-resonant search coil to monitor the transmit (B_1) field directly. This search coil had previously been calibrated using a concentrated ^{19}F phantom in place of the subject's head. The homogeneity provided by the use of a body transmitter coil ensured that this positioning was not critical.

Continuous data collections were made, each comprising 128 averages (256 for the initial study), with collection starting within 400 μs of the pulse and a repetition time of 1 s. During the sequence of experiments, presaturation sequences were designed which would eliminate the magnetic resonance signal from an operator-selectable plane. They were used in the last two experiments, interleaved with the standard sequences, in an attempt to eliminate the signal from the superficial tissues.

The MRS peak height data collected during the period of elimination were normalized to peak height before isoflurane was stopped and modelled by one, two and three exponential equations. The F test criterion advocated by Boxenbaum, Riegelman and Elashoff[16] was used to decide which model was supported best by the data. Conventionally, the significance of such curve fitting can be improved by pooling data from different subjects: the number of data points is increased but the number of variables to be fitted is unchanged. The coefficients and rate constants of the curve derived from the pooled data are then group coefficients and group rate constants. Unfortunately, our data were in arbitrary units which differed between subjects because the signal strength was so sensitive to the position of the surface coil, and there was no prospect of obtaining meaningful group coefficients. None the less, individual curve fitting can be undertaken simultaneously with the constraint that they all have the same rate constants (the group rate constants) with individual coefficients and group rate constants chosen to provide the best fit. The fit of single and biexponential equations to the pooled data can then be tested by the same F test criterion used for individual data sets. All curve fitting was performed by iteration using the Solver function of a Microsoft Excel v4 spreadsheet, with least squares solutions approximated from several initial variable values and checked visually to ensure that true minima had been found.

Results

A total of eight studies were undertaken on five volunteers (see table 1, fig. 1). Only five studies produced wash-out data. The other studies were terminated prematurely because the subject became restless before regaining consciousness. When this happened the subject was withdrawn immediately from the magnet bore and wash-out data were lost.

When each experiment was analysed individually, a biexponential equation was a significantly better fit to the data than a single exponential in only two experiments (table 1). However, when the data sets were pooled, there was strong overall support for biexponential decay ($P<0.00001$). No data set supported a three-exponential equation.

Presaturation pulses were used in two studies but

Table 1 Results of the studies undertaken in five volunteers

Subject No.	Concentration and duration of isoflurane	Wash-out data points	$T_{1/2}$, fast	$T_{1/2}$, slow	Signif. of 2 exponentials	Comments
1	0.25%, 10 min + 0.5%, 35 min	8	—	57	ns	Initial study. 5-min data acquisition
2	0.6%, 2 5min	17	4.7	92	0.002	2-min data acquisition for this and all following studies
3	1%, 30 min	30	5.9	74	0.00001	
4	1%, 30 min	12	—	25	ns	Presaturation pulses obliterated all signal
5	1%, 35 min	12	—	121	ns	Presaturation pulses obliterated all signal
Group		79	9.5	130	0.00001	The best fit when the model for each data set was constrained to share group half-times

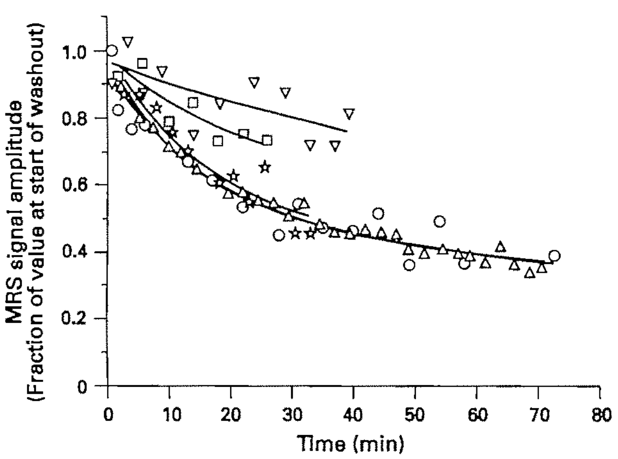

Figure 1 Wash-out of the ^{19}F MRS signal for each of the five subjects. Each subject's data are expressed as a fraction of the signal amplitude at the start of wash-out. Also shown are the biexponential curves of best fit, assuming all subjects shared the same fast and slow elimination half-times.

the signal was so diminished that peak heights could not be distinguished from noise.

Discussion

This study was undertaken because of inconsistencies in results from animal experiments and their deviation from the theoretical prediction of an elimination half-time of 5–10 min. In 1983, Wyrwicz and colleagues made the first *in vivo* observations of the kinetics of inhalation anaesthesia in rabbits using ^{19}F MRS.[9] They reported prolonged elimination of halothane from the brain with a half-time of several hours. These results were challenged by Strum, Johnson and Eger,[17] arguing from *in vitro* studies, but it was not until 1987 that further ^{19}F MRS studies appeared. Wyrwicz's group found biexponential elimination kinetics for halothane[18] and isoflurane[13] (the faster having a half-time of 25 min for both agents), but as both components were detected after surgical removal of extracranial tissues it was still concluded that there was a slow component to the elimination of anaesthetics from the rabbit brain with a half-time of 3–5 h. Litt and colleagues, using a different MRS technique to eliminate the signal from surface tissues, also found biexponential elimination kinetics of halothane from rat brain but the half-times were only 6 and 23 min.[19] The same group also studied the elimination of isoflurane from rabbit brain.[12] They found that elimination had a single component (half-time 36 min) when the skull was removed and a small surface coil applied directly to the brain, but two half-times of 55 min and 5 h in a single animal when a larger coil (matching that used by Wyrwicz and colleagues) was applied to the intact head. Their conclusion was that the long elimination half-time found by Wyrwicz and colleagues arose from tissue outside the brain, but their fast component results still disagreed with theory. They later compared the kinetics of halothane, isoflurane and desflurane in craniectomized rabbits, producing data compatible with perfusion-limited kinetics (half-times of approximately 8 and 60 min for all agents). Litt's group also produced images showing halothane exclusively in non-brain structures within the rabbit head,[20] although the MRS collection variables biased this study towards these areas. The opinions of these two groups remained unresolved, with each still vigorously defending their position in 1991,[10,11] but others were prepared to accept the fast component of halothane elimination from the rat head as an indicator of cerebral blood flow.[21]

Recently, Xu and co-workers found two-compartment kinetics for sevoflurane in the rat head with half-times of 14 and 100 min.[22] Sequential fluorine images showed initial accumulation of sevoflurane in brain, and one MRS characteristic of the two compartments (their T_2) provided further evidence that the fast compartment was the brain. Although the weight of evidence from animal work may now suggest that elimination of fluorinated anaesthetics from the brain is rapid, Wyrwicz and colleagues maintain that there is slow elimination from the brain, and the studies from Litt's group have not been consistent.[12,14] Even the results of Xu and colleagues, although technically impressive, give a half-time of sevoflurane elimination from the rat brain which is twice that expected from simple pharmacokinetic theory.

This is the first ^{19}F MRS study of the kinetics of inhalation agents in humans. Inhalation of isoflurane to the point of unconsciousness, and subsequent recovery, may be associated with restlessness, confusion and loss of airway control. It is therefore difficult to perform these experiments in the bore of a magnetic resonance spectrometer because the subject lies within a tunnel 6 ft long and 30 inches in diameter. Restlessness demands that the experiment be terminated so that the subject can be withdrawn from the magnet bore for safety, but any change in position of the subject's head relative to the receive coil invalidates further data collections. The studies therefore have some risk and a poor data yield. Nevertheless the investigation was pursued because human studies alone allow anaesthetic effects on consciousness to be related to tissue compartment concentrations: animal experiments are performed with background i.v. anaesthesia. This aspect of the study is reported in part II of the study.[15]

We have found evidence of biexponential wash-out of isoflurane from the head. The longer averaging used in the pilot study precluded the identification of a fast component of elimination, but the next two studies produced consistent data supporting two compartments. The improvement obtained by fitting a two- rather than a one-compartment model was not statistically significant in the last two subjects. This may be because fewer data points were collected from these experiments (the experiment was terminated when the subject became too restless), but there is another possible explanation. During this series of experiments the spectrometer was overhauled and modified, which included installation of electronic decoupling between receive and transmit coils (the previous decoupling was geometrical). An incidental result of the improved decoupling was to reduce the sensitivity of the surface coil to deeper tissues and if, as we believe, the fast component is deep, it would be more difficult to identify in the total signal. The timetable for hardware modifications to the spectrometer was unfortunately not under our control. In order to determine the overall significance of our evidence for biexponential elimination, we argued that regional perfusion of the head (which determines the kinetics of the underlying compartments) would be similar between subjects and that the more variable parameters would be the relative strength of the signal from the compartments because this depends critically on the exact position of the coil relative to the scalp, cranium and brain. We therefore re-computed the best fitting single and biexponential equations for all of our subjects simultaneously, subject to the constraint that all five shared the same half time(s). This analysis gave strong support for biexponential elimination.

The presaturation pulses were intended to resolve the two components spatially. Ideally the plane of the pulse obliterating the MR signal would have been so sharply defined that signal from adjacent areas was unaffected. Some encroachment into brain tissue was inevitable, but we thought that enough signal would remain to estimate isoflurane kinetics in purely brain tissue. In the two studies for which presaturation sequences were available there was no significant fast component and it is not surprising that almost all the signal was lost after presaturation of the superficial plane. This part of the study therefore only enables us to say that most of the signal is superficial, as is inevitable with a surface coil, and in particular we cannot refute the claim that there is a slow component in the deeper structures. None the less, the match of experimental and computer-generated results suggests that the fast compartment is brain and the slow is superficial tissue.

Our half-times were substantially shorter than those reported from most animal studies. This may be explained by species differences, but there were experimental differences which may also have contributed. Our subjects were exposed to isoflurane for relatively short durations; slow compartments would not have absorbed much isoflurane and their contribution to the MRS signal would be modest even though the ^{19}F signal from non-cerebral tissues decays more slowly and can be collected more efficiently (technically, it has a longer T_2 in these tissues). In a longer experiment the signal from a small, fast compartment could be drowned by the signal from slower compartments with greater affinity for isoflurane, lying closer to the surface coil. Our 6 cm surface coil was smaller relative to the brain than coils used in animal experiments so that it should have relatively more brain in its region of sensitivity, and our sampling rate of 2 min was shorter, making it easier to identify faster processes. Indeed, if we had continued to average over 4 min as in the pilot study, we may not have obtained statistical justification for biexponential elimination. Thus although the underlying kinetics in humans and animals are probably similar, different experimental designs have been biased towards different subprocesses.

Although we have data from only a few studies, our results match the expectation of practising anaesthetists and support the classical perfusion-limited pharmacokinetic theory of inhalation anaesthesia. We feel that because of the inherent risks of the study and the low yield, further human experiments should await improvement in the MRS technique.

Summary

We describe the first experiments to relate the cerebral kinetics of isoflurane (determined by fluorine magnetic resonance spectroscopy) to cerebral function. Using a surface receive coil we found two-compartment kinetics within the head with equilibrium half-times of 3.5 min and approximately 1 h with respect to expired isoflurane concentrations. Using critical fusion flicker frequency as an objective measure of the cerebral effect of isoflurane, we found evidence to identify the fast component as the brain. Responsiveness to command was lost at a brain partial pressure of 0.3% isoflurane. We conclude that the measured cerebral kinetics of isoflurane exactly matched the predictions of the classical perfusion-limited model. (*Br. J. Anaesth.* 1997; **79**: 586–589).

Key words
Anaesthetics volatile, isoflurane. Pharmacokinetics, isoflurane. Measurement techniques, magnetic resonance spectroscopy.

The tissue kinetics of isoflurane can be followed *in vivo* by fluorine magnetic resonance spectroscopy (^{19}F MRS). The first part of this study[1] reported the first such measurements in humans and demonstrated biexponential elimination from the head, which supports the predictions of the standard, perfusion-limited pharmacokinetic model. The concentration of isoflurane was too small to confirm spatial localization by ^{19}F magnetic resonance imaging, so in this part we report our experience with functional localization, that is relating tissue compartment concentrations of isoflurane deduced from MRS data to their cerebral effect. Such studies can only be performed in human subjects.

Subjects and methods

Most of the details of the subjects and methods have been reported in part I of this study[1]; only an overview and additional details are given here. In essence, volunteers were placed in a magnetic resonance spectrometer and breathed 0.6–1% isoflurane in oxygen. The end-expired isoflurane concentration was measured by an infrared analyser. A coil placed over their occiput collected MRS data. With this arrangement the amount of signal depends on the amount of isoflurane in the coil's receptive field, but the shape and regional sensitivity of this field is not known exactly.

Subjects were attended by two anaesthetists: one remained outside the spectrometer's radio frequency screening enclosure watching the electronic monitors, the other was inside the enclosure monitoring respiration and assessing the level of sedation by prompting the subject to press a communication bleeper at 1-min intervals. After the fourth experiment a system for monitoring critical flicker fusion (CFF) was included in the study. A red LED placed against a black background on the side wall of the bore of the magnet was observed by the subject who held a micro switch. Wires from these were passed through radio frequency filters to a computer which controlled the rate of flicker from outside the spectrometer. The flicker decreased by 1 Hz every second from 45 Hz until the subject pressed the micro switch to indicate that the flickering was visible. This fusion flicker frequency was stored on hard disk, the LED turned off for 3 s, then the process repeated. CFF is conventionally the average of fusion flicker (decreasing rate of flicker) and flicker fusion (increasing rate of flicker) frequencies. We were unable to measure the flicker fusion frequency contemporaneously because heavily sedated subjects confused flicker fusion runs with fusion flicker runs. The simple instruction to "Click when it flickers" was the most such subjects could manage in the relative isolation of the magnet bore.

An intra-arterial cannula was sited in four studies of three subjects. After a short period during which baseline measurements were made, a constant concentration of isoflurane (0.6–1%) was introduced into the inspired gas. Arterial blood analysis was used to confirm that the end-expired isoflurane concentration was being measured accurately in gas

aspirated along a 6-m catheter, using a technique similar to that described by Landon and colleagues[2] and modified later in our laboratory.[3]

A computer model of up to three parallel compartments was also developed in which the isoflurane partial pressure in each compartment was increased or decreased in proportion to the difference between the measured end-expired and modelled compartment partial pressures. Specifically:

$$P_i(t+1) = P_i(t) + (P\text{E}'(t) - P_i(t) \times k_i \times \delta_i$$

where $P\text{E}'(t)$ and $P_i(t)$=partial pressures in expired gas and the *i*th compartment, respectively at time *t*; k_i=compartment rate constant; δ_i=time interval between *t* and *t*+1. δ_i was 10 s—the interval between consecutive data sets from the gas analyser. The model total MRS signal is given by:

$$\text{MRS model}(t) = \Sigma^n{}_{i=1}\ W_i \times P_i(t)$$

where W_i=weighting factor of the ith compartment and *n*=number of compartments used in the model. The weighting factor may be considered as the product of a pharmacokinetic factor (which depends on the capacity of the compartment for isoflurane) and a spatial scaling factor (which depends on the regional sensitivity of the coil to the MR signal). These two components are constant in time. The least squares fit of the model to the actual MR data was made by manipulating one pair of variables for each compartment: the rate constant (k_i) and a weighting factor (W_i) for the contribution of that compartment to the total MRS signal. All modelling was performed by iteration using the Solver function of a Microsoft Excel v4 spreadsheet, with least squares solutions approximated from several initial variable values and checked visually to ensure that true minima had been found. The *F* test criterion of Boxenbaum, Riegelman and Elashoff[4] was used to determine the number of compartments appropriate for each subject's data.

The model enabled us to use all data acquired during complete studies, and the early data collected during studies which were terminated prematurely because of restlessness before wash-out data were collected. Furthermore, because the wash-in and wash-out data were modelled to the expired gas concentration, the effect of changes in ventilation on the elimination of isoflurane did not affect the rate constants for the compartments identified by the model.

During dynamic studies such as these, hysteresis between drug concentrations in different locations and their biological effect provide evidence of the site of drug action: lack of hysteresis is circumstantial evidence of site of effect. When CFF frequency results were available during both wash-in and wash-out they were plotted as functions of isoflurane concentrations in either expired gas or the tissue compartments and inspected for evidence of hysteresis.

We also sought evidence of hysteresis between losing and gaining responsiveness to command. The actual brain isoflurane concentrations at these moments should have small variance. We therefore normalized each group of data (expired gas, fast and slow compartments) by dividing by its mean and compared variances by the *F* test.

Results

A total of eight studies were undertaken on five volunteers (see table 1). Expired isoflurane concentrations were not stored during our pilot study, and therefore these data cannot be used here. Only four studies produced both wash-in and wash-out MRS data and an example is shown in figure 1. In most instances the other studies were terminated prematurely because the subject became restless before regaining consciousness. When this happened the subject was withdrawn immediately from the magnet bore and wash-out data were lost. In one study the first measured ^{19}F signal was greater than those immediately after. Although no cause could be found at the time, this was assumed to be a technical problem and the study was abandoned. For safety, the subject was removed from the magnet bore and allowed to recover under direct observation so that wash-out data could not be acquired. Analysis of those MRS data (excluding the first measurement)

Table 1 Results of the eight studies undertaken in five volunteers

Subject No.	No. of data points	$T_{1/2}$, fast	$T_{1/2}$, slow	Signif. of two compartments	Comments
1	—	—	—	—	Expired gas not measured so data not usable here
2	22	5.9	96	0.001	Complete MRS data set
1	40	1.8	65	0.001	Complete MRS data set
2	8	—	48	ns	No wash-out data (study terminated because of presumed technical failure)
1	22	2.4	41	0.001	No wash-out data (subject removed from scanner because of movement). CFF data collection continued and analysed against extrapolated fast compartment signal
3	13	—	30	ns	Subject moved while heavily sedated and so withdrawn briefly from spectrometer before a second attempt, also unsuccessful. Procedure abandoned and no wash-out data collected. Both wash-in data sets analysed together
4	21	—	16	ns	Complete MRS data set. Baseline CFF too variable to make data useful
5	19	3.9	263	0.005	Complete MRS data set. Consistent CFF
Group	145	4.8	135	0.00001	The best fit when the two-compartment model for each data set was constrained to share group half-times

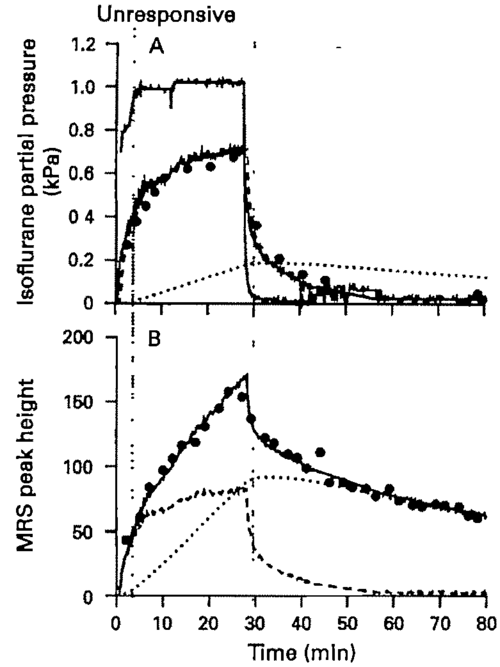

Figure 1 An example study (subject No. 2). A: Partial pressure of isoflurane measured in inspired gas (upper continuous line), expired gas (lower continuous line) and arterial blood (●). Broken and dotted lines show the partial pressure of isoflurane calculated to be in the fast and slow compartments, respectively, as derived from the magnetic resonance (MR) data. B: Actual MR data in arbitrary units (circles), the total of the two-compartment model (continuous line) and the fast (broken line) and slow (dotted line) components of the model.

showed single compartment kinetics and it seems likely that signal was received initially from the fast compartment but then the subject moved, displacing the surface coil so that it collected data from superficial tissues only.

Arterial partial pressures were measured in four studies of three subjects. During wash-in, values were 80–95% of end-expired partial pressures. There was a similar, but reversed, gradient during wash-out.

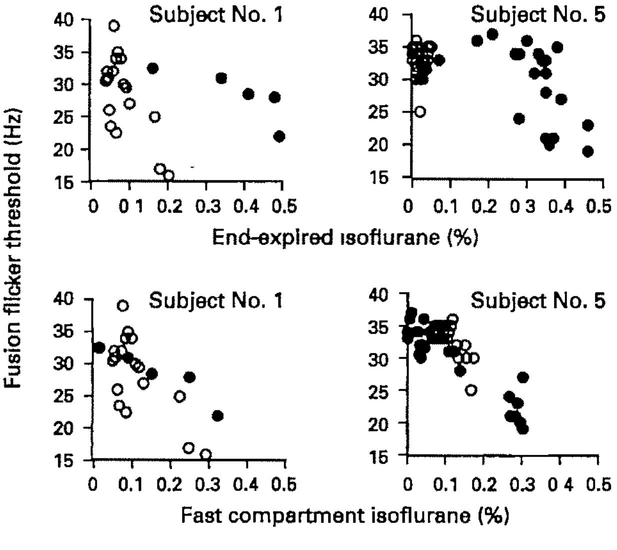

Figure 2 Critical fusion flicker (CFF) frequencies for two subjects (Nos 1 and 5) from whom data were available during both wash-in and wash-out of isoflurane. In the upper plots CFF is displayed as a function of isoflurane measured in expired gas, in the lower plots as a function of isoflurane concentration calculated to be in the fast component, as derived from magnetic resonance data. Solid symbols indicate data recorded during wash-in, open symbols during wash-out. Note that the obvious hysteresis in the upper plots is absent in the lower plots.

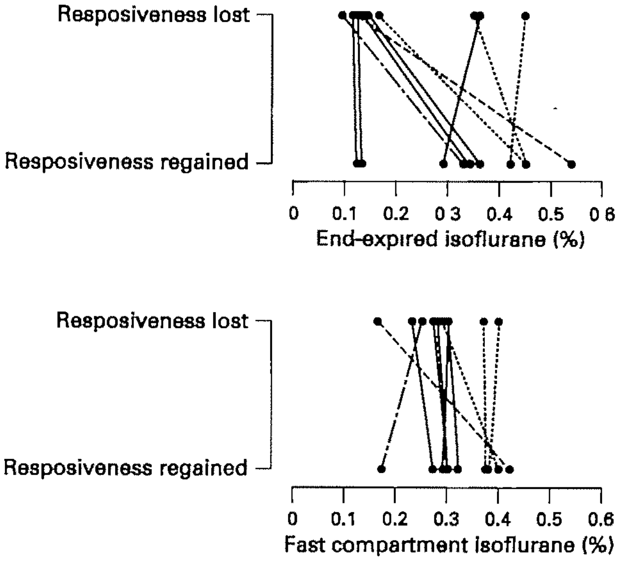

Figure 3 Isoflurane concentrations in end-expired gas and the fast component (calculated from the magnetic resonance data) at the moments of losing and next regaining responsiveness to command. Data from four subjects, two of whom aroused spontaneously during the study and contributed multiple data points (—=subject No. 1; -·-=subject No. 2; ...=subject No. 4; continuous=subject No. 5).

Four of the seven sets of data modelled against expired isoflurane concentration supported a two-compartment model ($P<0.005$), giving a mean of 3.5 min for the fast half-time (table 1). As both wash-in and wash-out measurements took place over a 40-min period each, processes with half-times greater than this period were poorly determined. No data set supported a three-compartment model. When the data were pooled, two-compartment models were strongly supported over one-compartment models ($P<0.00001$) with group rate constants equivalent to half-times of 4.8 and 135 min.

Only two studies produced CFF data during both wash-in and wash-out. These are shown together in figure 2. Hysteresis is clearly present in the plot of CFF against expired isoflurane, but this is absent when CFF is plotted against isoflurane in the fast compartment.

Four subjects lost and regained responsiveness to command while in the spectrometer (fig. 3), two of these on more than one occasion as irregular respiration caused the expired isoflurane concentration to increase and decrease. When normalized by division by the group mean, the variance in the fast compartment was less than in the expired gas ($P<0.0005$) or the slow compartment ($P<0.00001$).

Discussion

The difficulties of clinical monitoring of patients in a spectrometer are now well understood and relatively easy to overcome.[5] Assessment of the conscious level of a subject in the magnet bore who cannot speak because of the mouthpiece, and is in any case required to keep as still as possible, remains troublesome and limits pharmacodynamic conclusions. As a crude indicator of consciousness, subjects operated a whistle by squeezing a hand-held bulb in response to a command from the attending anaesthetist. This requires consistent verbal delivery of the command which must gain the subject's attention without startling him (which could precipitate movement). CFF is a more refined measure of cognitive impairment and was introduced later in the series of experiments. We decided that alternatives such as response time would risk movement artefact in sedated subjects.

Respired gas was sampled close to the mouth from a breathing system which depended on careful placement and facial tone to maintain a seal at the mouth. The sample was obtained along a 6-m line, which increases both transit and response times of the Datex Ultima. The accuracy of our measurements of isoflurane in end-expired gas is therefore open to question, so we obtained frequent arterial blood samples during four studies. In general we found that during wash-in arterial partial pressures followed measured expired gas partial pressures with a brief lag and small gradient, similar to the findings of other investigators.[6 7]

We have found evidence of two tissue compartments filling from the isoflurane tension in alveolar gas. The surface coil we used collected MRS data from a region of the head, including skin, fat, bone and brain, by acting as an aerial over the occiput. Three factors affect the fluorine MRS signal received from each tissue: the concentration of isoflurane within the tissue, its proximity to the receive coil and the chemical environment of the fluorine atoms in that tissue. Pharmacokinetic theory can predict the concentration of isoflurane in each tissue, but the contribution to the total MRS signal cannot be determined *a priori*. The weights calculated for each compartment therefore hold no clue as to their physical representation which remains undetermined because the MRS signal in our experiments was too weak to allow imaging. Our data strongly support the brain as the source of the fast compartment signal because (i) the kinetics of our model matched well those predicted by classical pharmacokinetic theory; (ii) the hysteresis observed when CFF was related to expired gas was lost when it is related to the fast compartment (although these data came from only two subjects); (iii) the moments of losing and regaining responsiveness were related to a relatively constant fast component isoflurane concentration. Although marked variation in anaesthetic distribution within the brain has been demonstrated on a small scale,[8] there is no evidence to suggest the existence of two compartments large enough to be detected by the spectrometer yet having such different kinetics. Anaesthetics are generally approximately half as soluble in grey as in white matter[9] so even with its greater perfusion,[10] the grey matter should equilibrate no more than six times faster. The fact that we obtained a fluorine signal from a single compartment when the coil was displaced also suggests that the slow compartment is superficial and spatially separated from the brain.

Although we have few complete studies they are in close agreement and are supported by our other results. The fast compartment correlates with objective measures of anaesthetic effect. We have sufficient confidence in these data to believe that further repetition—with the potential risks to the subjects—is not justified until technical improvements allow localization of the signal. Our findings support the classical perfusion-limited pharmacokinetic theory of inhalation anaesthesia.

Differential effects of nitrous oxide and propofol on myogenic transcranial motor evoked responses during sufentanil anaesthesia†

L. H. UBAGS, C. J. KALKMAN, H. D. BEEN AND J. C. DRUMMOND

Summary

We have compared the effects of 50% nitrous oxide and propofol, each administered concurrently with sufentanil, on the amplitudes and latencies of the compound muscle action potential (CMAP) response to transcranial electrical stimulation. Using a crossover design, 12 patients undergoing spinal surgery were exposed to both 50% nitrous oxide and propofol, the latter in a bolus–infusion regimen. Six patients received nitrous oxide first and six received propofol first. CMAP were recorded from the tibialis anterior muscle in response to both single and paired transcranial electrical stimuli. With single pulse stimulation, median CMAP amplitude was significantly greater during administration of nitrous oxide than propofol (nitrous oxide 335 (10th–90th percentiles 35–849) µV; propofol 36 (0–251) µV) ($P<0.01$). With paired stimulation, there was no significant difference in CMAP amplitude during the two regimens (nitrous oxide 1031 (296–1939) µV; propofol 655 (0–1867) µV). The results indicate that propofol caused more depression of transcranial electrical motor evoked responses than 50% nitrous oxide but that the difference was probably clinically unimportant when a paired stimulation paradigm was used. (*Br. J. Anaesth.* 1997; **79**: 590–594).

Intraoperative monitoring of motor evoked responses to transcranial electrical or magnetic stimulation (tc-MER) provides a method of assessing the integrity of ventral motor columns during operations in which there is a risk of spinal cord injury.

A difficulty with intraoperative tc-MER monitoring lies in the considerable tc-MER amplitude depression that occurs with most anaesthetic regimens. At least with single stimuli, the use of relatively low concentrations of volatile anaesthetics (0.2–0.3% end-tidal isoflurane[1 2]) precludes intraoperative tc-MER monitoring. Nitrous oxide,[3] benzodiazepines,[4 5] barbiturates and propofol[5] have been shown to depress tc-MER amplitude. Drugs that have been shown to have only minor effects on tc-MER are those known to maintain or increase muscle tone, for example etomidate,[5] ketamine and synthetic opioids.[5]

Currently, two anaesthetic regimens are used widely during surgery in which myogenic responses to transcranial stimulation are used for spinal cord motor tract monitoring. Some groups have successfully used nitrous oxide–opioid anaesthesia.[2 3 6] Others have advocated propofol–opioid total i.v. anaesthesia (TIVA).[7] These two anaesthetic techniques have not been compared previously with respect to the relative magnitude of tc-MER depression.

The purpose of this crossover study was to determine the relative effects of nitrous oxide and propofol on tc-MER amplitude, amplitude variability and onset latencies. As it was shown recently that multiple stimuli may improve the efficiency of transcranial stimulation,[8–11] comparison of the two anaesthetic regimens was performed with both single and paired stimuli.

Patients and methods

Written informed consent for this institutionally approved study was obtained from 12 patients (seven females, aged 14–64 yr) undergoing orthopaedic spinal surgery.

Transcranial stimulation was performed using two identical Digitimer D180A transcranial electrical stimulators (Digitimer Ltd, Welwyn Garden City, UK), triggered either simultaneously (single pulse stimulation) or sequentially with an inter-stimulus interval of 3 ms (paired stimulation). The outputs from both units were combined via diodes and delivered to the scalp via 9-mm silver EEG disk

electrodes. The anode was positioned at Cz and the cathode consisted of interconnected electrodes at Fz, A1 and A2 (international 10–20 system).[12] Myogenic responses were recorded over the left and right tibialis anterior muscles, using adhesive gel silver–silver chloride electrodes (Cleartrace, Medtronic Andover Medical Inc., Haverhill, MA, USA). The active electrode was placed over the muscle belly, referenced to an electrode placed over the tendon. The signal was amplified 5000–20 000 times (adjusted to obtain maximum vertical resolution), and filtered between 30 and 1500 Hz using a 3T PS-800 biologic amplifier (Twente Technology Transfer, Twente, The Netherlands). These amplifiers have a very high input impedance ($>10^{12}$ Ω) and common mode rejection ratio (greater than 95 dB). The responses were sampled at 2 kHz, displayed and stored on a Macintosh Quadra computer (Apple Computer, Cupertino, CA) with 12 bit A/D conversion and MER acquisition software written with the LabView data acquisition development system (National Instruments, Austin, TX, USA).

In both groups anaesthesia was induced with etomidate 0.3 mg kg^{-1} and a loading dose of sufentanil 1.5 μg kg^{-1}, followed by continuous infusion of 0.5 μg kg^{-1} h^{-1}. Intubation of the trachea was facilitated by vecuronium 0.1 mg kg^{-1}. Neuromuscular block was monitored electromyographically at the hypothenar eminence using a Datex Relaxograph (Datex, Finland). This device applies a train-of-four stimulus to the ulnar nerve every 20 s and displays the height of the first response (T1 %), and the train-of-four ratio (T4/T1 %). After the amplitude of T1 had recovered to 20% of control, neuromuscular block was maintained at this level throughout surgery with vecuronium using a closed-loop infusion system. This level of neuromuscular block at the hypothenar muscle produces a T1 of 60% at the tibial anterior muscle.[13]

Routine anaesthetic monitoring included ECG, Sp_{O_2}, invasive arterial pressure, central venous pressure, end-tidal carbon dioxide concentration and nasopharyngeal temperature.

The order in which patients received nitrous oxide or propofol was randomized. After induction of anaesthesia, 50% of patients received 50% nitrous oxide in oxygen until 60 min after skin incision. Thereafter, administration of nitrous oxide was discontinued and propofol 1 mg kg^{-1} administered i.v., followed by an infusion at a rate of 10 mg kg^{-1} h^{-1} for the first 10 min, 8 mg kg^{-1} h^{-1} for the next 10 min and 6 mg kg^{-1} h^{-1} for the remainder of the procedure. This infusion results in blood propofol concentrations of approximately 3 μg ml^{-1}.[14]

In the other six patients, anaesthesia was maintained initially with propofol, using the infusion regimen described above. Sixty minutes after skin incision, the propofol infusion was discontinued and replaced by 50% nitrous oxide in oxygen.

Tc-MER stimulus intensity was determined after induction of anaesthesia with etomidate and was set at just supramaximal to single pulse stimulation (typically 500–700 V). The tc-MER recordings were made over a 30-min period, starting at least 20 min after skin incision, or 30 min after the crossover. Compound muscle action potentials (CMAP) to single and paired stimulation were acquired in a 1-min period every 3 min during the study. For each regimen and stimulation paradigm, the median amplitude from 10 responses, recorded every 3 min, was calculated and compared using the Wilcoxon signed rank test. Amplitudes are presented as median (10th and 90th percentiles) and latencies as mean (SD).

To estimate within-patient variability, we calculated the coefficient of variation (cv) from 10 responses. The cv were compared using the Wilcoxon signed rank test and are expressed as median (10th and 90th percentiles).

Each patient was questioned specifically for recall of intraoperative events immediately after surgery and on the following day.

Results

Figure 1 shows representative triplicate CMAP to paired and single pulse transcranial stimulation during both anaesthetic regimens in one patient.

SINGLE PULSE STIMULATION

During nitrous oxide–opioid anaesthesia, reproducible responses with single transcranial stimuli were recorded in 11 of 12 patients, whereas during propofol–opioid TIVA, tc-MER were recordable in seven of 12 patients. During the nitrous oxide regimen, tc-MER amplitude was 335 (35–849) μV and latency to onset 33.9 (3.9) ms. With propofol, tc-MER amplitude was 36 (0–251) μV ($P<0.01$) and latency 34.4 (3.4) ms. There was no significant difference in onset latency between the two anaesthetic regimens.

PAIRED STIMULATION

During nitrous oxide–opioid anaesthesia, tc-MER to paired stimulation were recordable in all patients, whereas tc-MER during propofol–opioid anaesthesia were elicited in 10 of 12 patients with paired stimuli. There was no significant difference in amplitude or onset latency between the two anaesthetic regimens. During the nitrous oxide regimen, tc-MER

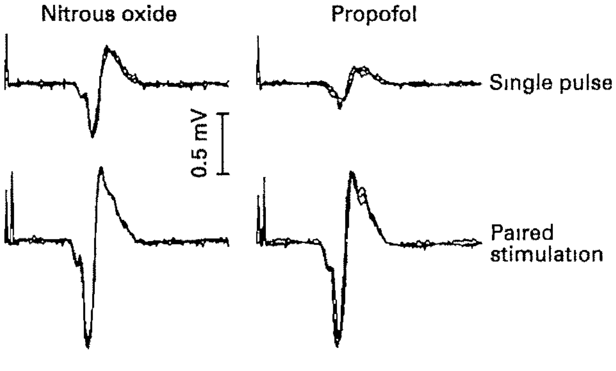

Figure 1 CMAP to paired and single pulse transcranial stimulation, during both anaesthetic regimens (nitrous oxide and propofol), in a patient undergoing orthopaedic spinal surgery Triplicate responses are superimposed to indicate reproducibility.

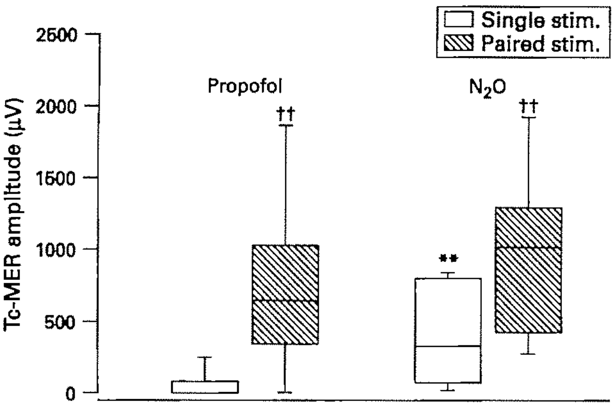

Figure 2 Box plots of tibialis anterior tc-MER amplitude to single or paired transcranial electrical stimulation during both anaesthetic regimens (nitrous oxide (N_2O) and propofol). Horizontal bars represent 90, 75, 50 (median), 25 and 10th percentiles. $^{**}P<0.01$ compared with propofol; $^{††}P<0.01$ compared with single pulse stimulation.

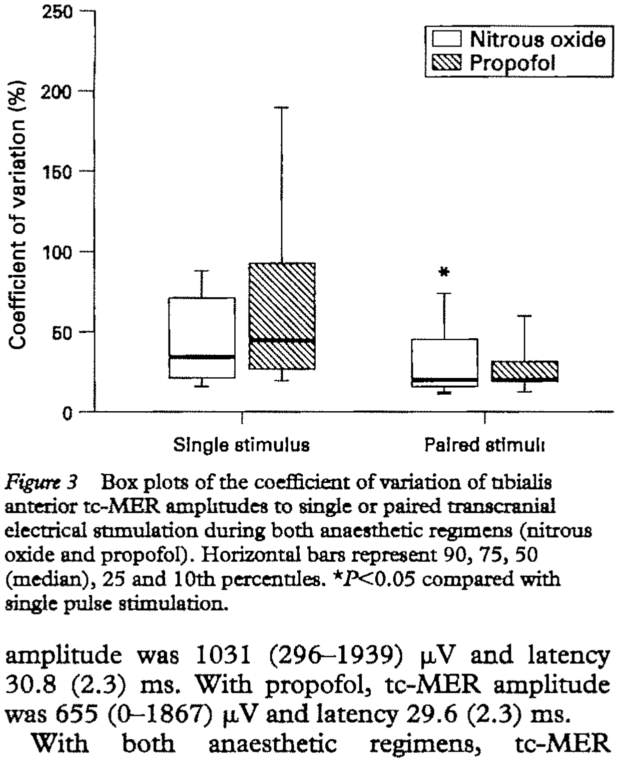

Figure 3 Box plots of the coefficient of variation of tibialis anterior tc-MER amplitudes to single or paired transcranial electrical stimulation during both anaesthetic regimens (nitrous oxide and propofol). Horizontal bars represent 90, 75, 50 (median), 25 and 10th percentiles. $^{*}P<0.05$ compared with single pulse stimulation.

amplitude was 1031 (296–1939) μV and latency 30.8 (2.3) ms. With propofol, tc-MER amplitude was 655 (0–1867) μV and latency 29.6 (2.3) ms.

With both anaesthetic regimens, tc-MER amplitude was significantly higher when paired transcranial stimulation was used ($P<0.01$) and onset latency was shorter ($P<0.01$). Figure 2 shows box plots of tibialis anterior tc-MER to single pulse and paired transcranial stimulation during both anaesthetic techniques.

There was no significant difference in the coefficient of variation for tc-MER amplitude between the two anaesthetic regimens (fig. 3). For the nitrous oxide–opioid regimen, cv was significantly less ($P<0.05$) with paired stimuli than with a single stimulus. During the propofol–opioid regimen there was a tendency ($P=0.08$) to a smaller cv with paired stimulation. With a single stimulus, the cv was 32% (12–85%) during nitrous oxide–opioid anaesthesia and 42% (15–190%) during propofol–opioid TIVA. When paired stimuli were used, the cv was 8% (18–71%) during nitrous oxide–opioid anaesthesia and 14% (9–57%) during propofol–opioid TIVA.

During the recording period, haemodynamic variables remained stable and there was no significant difference in heart rate (HR) or mean arterial pressure (MAP) between the two anaesthetic regimens. During propofol–opioid anaesthesia, mean HR was 76 (SD 6.4) beat min^{-1} and MAP 83 (10.1) mm Hg; during nitrous oxide–opioid anaesthesia, HR was 78 (8.2) beat min^{-1} and MAP 81 (12.3) mm Hg. None of the patients experienced recall of intraoperative events.

Discussion

The data derived from this study indicate that at the doses used, propofol–opioid TIVA depressed the amplitude of myogenic responses to electrical transcranial stimulation more than nitrous oxide–opioid anaesthesia. Although there was no significant difference in amplitude between both anaesthetic regimens when paired transcranial stimuli were used, tc-MER were not recordable in two of 12 patients during propofol, while during nitrous oxide, tc-MER were recordable in all patients. Although nitrous oxide is a potent depressant of myogenic tc-MER, most authors were successful in obtaining reproducible myogenic responses to transcranial stimulation, provided relatively low concentrations of nitrous oxide were used. Zentner and Ebner have examined the effects of increasing nitrous oxide concentrations on motor evoked responses to cortical and mid-cervical electrical stimulation, recorded from the thigh muscles in six rats.[15] They observed a 45% reduction in amplitude with an end-tidal nitrous oxide concentration of 50%; at 66% end-tidal nitrous oxide, the myogenic signal was completely abolished.

Ghaly and co-workers have examined the effects of nitrous oxide on magnetic tc-MER recorded from the fore- and hindlimb flexor muscles in 16 cynomolgus monkeys. They were able to record tc-MER in all animals with nitrous oxide concentrations up to 75%. However, with 75% end-tidal nitrous oxide, tc-MER amplitude was significantly decreased and stimulation threshold intensity increased, compared with 25% and 50% end-tidal nitrous oxide.[16]

Woodforth and colleagues studied variability of tibialis anterior tc-MER to electrical stimulation in six patients undergoing surgery for correction of scoliosis.[17] Anaesthesia was maintained with fentanyl and 70% nitrous oxide in oxygen. The authors recorded responses to single pulse stimulation in all patients although amplitude was very low (mean of 100 responses <50 μV in all patients). However, with these high concentrations nitrous oxide tc-MER amplitude is depressed substantially and variability increases to such an extent that reliable spinal cord monitoring may not be possible.

In contrast, most studies which have described clinical tc-MER monitoring during propofol anaesthesia showed a smaller success rate in obtaining a reproducible myogenic response. Kalkman and co-workers examined the effects of a bolus dose of propofol 2 mg kg^{-1} on electrical and magnetic tibialis anterior tc-MER in five healthy volunteers.[5]

Two minutes after administration of propofol tc-MER amplitude decreased to 2.2 (SD 0.9) % of baseline; 30 min after administration, tc-MER amplitude was still depressed (44 (18) %). There was no effect on onset latency.

Jellinek, Jewkes and Symon studied tc-MER in 26 patients undergoing surgery for a unilateral prolapsed disc during propofol TIVA.[7] CMAP to electrical transcranial stimulation were recorded from the first dorsal interosseous muscle of the foot of the asymptomatic leg or from the second dorsal interosseous muscle of the hand. After an induction dose of 2 mg kg^{-1}, anaesthesia was maintained with a continuous infusion at a rate of 10–12 mg kg^{-1} h^{-1}. They were able to elicit reproducible tc-MER in 23 of 26 patients (88.5%), but tc-MER amplitude was 7% of awake control values (obtained with a magnetic transcranial stimulator).

Taniguchi and colleagues studied the effects of propofol on magnetic tc-MER recorded from the abductor pollicis brevis muscle in 22 patients undergoing surgery for lumbar disc herniations.[18] They used a fixed infusion scheme, designed to reach a plasma propofol concentration of 1.5 $\mu g\ ml^{-1}$ within 15 min. Fifteen minutes after the start of propofol infusion (cumulative dose 128 mg) tc-MER were preserved in only three of 22 cases (14%). Jones and colleagues were able to record reproducible myogenic responses of at least 100 μV to trains of three to six transcranial responses during propofol–nitrous oxide–alfentanil anaesthesia, whereas single pulse stimulation failed to elicit reproducible responses.[19]

It is conceivable that the propofol–opioid and the nitrous oxide–opioid regimens were not equipotent and that the propofol–opioid regimen used in this study provided a deeper level of anaesthesia than the nitrous oxide–opioid technique. This could explain the observed difference in tc-MER amplitudes during both anaesthetic regimens. It is likely that a deeper level of anaesthesia results in more amplitude depression because most anaesthetics that depress tc-MER do so in a dose-dependent manner. Unfortunately, there is no method to reliably quantify the "level of anaesthesia" in a clinical setting and we are therefore unable to determine if the observed differences in tc-MER depression were the result of a difference in depth of anaesthesia. The analgesic component consisted of constant infusions of sufentanil and was similar in both regimens. Inadequate anaesthesia, as suggested by increases in heart rate and arterial pressure, did not occur during each regimen and no patient had recall of intraoperative events.

This study confirms previous results that the use of paired transcranial stimulation partly overcomes the anaesthetic-induced depression of the myogenic response during nitrous oxide–opioid[10] and isoflurane anaesthesia.[11] The observed amplitude augmentation with paired stimuli is most likely the result of temporal summation; the first stimulus lowers the excitation threshold of the cortical and spinal motor neurones, thereby facilitating initiation of neuronal discharge by the second stimulus.[10] It is conceivable that stimulation with more than two successive pulses might further increase intraoperative tc-MER amplitudes and result in a greater success rate of tc-MER monitoring during propofol–opioid anaesthesia. Kawaguchi and co-workers described the effects of single pulse and train-of-five electrical stimulation of the exposed motor cortex on the tibialis anterior myogenic response during an anaesthetic regimen consisting of nitrous oxide and isoflurane or sevoflurane.[11] With train-of-five stimulation they were able to record tc-MER in all patients with concentrations of the volatile anaesthetic up to 1.5 times the minimum alveolar concentration.

The results of this study also suggest that the reproducibility of myogenic tc-MER increases when paired stimuli are used. Within-patient variability, expressed as cv, decreased when two pulses were used; this decrease was more pronounced during nitrous oxide–opioid anaesthesia than during propofol–opioid TIVA. It is likely that the decrease in cv during opioid–propofol TIVA was not statistically significant because of the small number of patients analysed (five patients had no response to a single stimulus during TIVA). It is conceivable that reproducibility increases because a higher tc-MER amplitude is obtained that is closer to the maximal response that can be obtained (the CMAP that results when all motor units are discharged).

In summary, we have demonstrated that during propofol–opioid TIVA, muscle responses to electrical transcranial stimulation were depressed more than during nitrous oxide–opioid anaesthesia. However, when paired stimulation was used, responses during both anaesthetic regimens were amplified considerably and the difference became clinically irrelevant in most patients. This suggests that when tc-MER monitoring is indicated, and there is concern about the adequacy of nitrous oxide–opioid anaesthesia, it is possible to use propofol–opioid TIVA, provided that a multiple stimulus paradigm is used. In a subset of patients, propofol–opioid TIVA may depress the motoneural system to such an extent that recordable tc-MER cannot be obtained, even when paired stimuli are used. When this occurs propofol may be substituted by nitrous oxide to allow tc-MER monitoring during stages of surgery in which spinal cord monitoring is imperative. Furthermore, it is likely that the use of more than two successive stimuli may increase the success rate of intraoperative tc-MER monitoring during propofol–opioid TIVA. The results of this study justify further clinical evaluation of the efficacy of multi-pulse transcranial stimulation during total i.v. anaesthesia.

Emergence times from xenon anaesthesia are independent of the duration of anaesthesia†

T. GOTO, H. SAITO, Y. NAKATA, S. UEZONO, F. ICHINOSE AND S. MORITA

Summary

Xenon (MAC=71%) has an extremely low blood:gas partition coefficient (0.14). Therefore, we predicted that the rate of emergence from xenon anaesthesia would not be affected greatly by duration of anaesthesia. We studied 54 ASA I–II patients undergoing lower abdominal surgery who received equal MAC anaesthesia with 60% xenon, 60% nitrous oxide with 0.5% isoflurane or 60% nitrous oxide with 0.7% sevoflurane (n=18 per group), each supplemented with extradural mepivacaine anaesthesia. Duration of anaesthesia was 58–380 min. At the end of operation, all inhalation anaesthetics were discontinued and patients were allowed to wake up while breathing oxygen spontaneously. A blinded investigator recorded the time until patients opened their eyes on command (T1), were judged ready for tracheal extubation (T2), could correctly state their name, date of birth and name of the hospital (T3), and could count backwards from 10 to 1 in less than 15 s (T4). Emergence times after xenon and nitrous oxide–sevoflurane anaesthesia did not correlate with duration of anaesthesia, whereas those from nitrous oxide–isoflurane had positive correlations. Mean emergence times from xenon anaesthesia were: T1, 3.3 (SD 1.0) min; T2, 3.6 (1.0) min; T3, 5.0 (1.1) min; and T4, 6.2 (1.7) min. These values were approximately 50% of those after nitrous oxide–sevoflurane anaesthesia (T1, 5.6 (1.4) min; T4, 10.5 (2.0) min). We conclude that xenon provided fast emergence from anaesthesia, regardless of the duration of anaesthesia. (*Br. J. Anaesth.* 1997; **79**: 595–599).

Key words
Anaesthesia, duration. Recovery, postoperative. Anaesthetics gases, nitrous oxide. Anaesthetics gases, xenon. Anaesthetics volatile, isoflurane. Anaesthetics volatile, sevoflurane.

Xenon, an inert gas with a clinically relevant anaesthetic potency (MAC=71%),[1] is extremely insoluble in human body tissues. Its blood:gas partition coefficient is 0.14,[2] significantly lower than those of other inhalation anaesthetics, including nitrous oxide (0.47), sevoflurane (0.65) and desflurane (0.42).[3] This property predicts that emergence from xenon anaesthesia is faster than that from other inhalation anaesthetics (which we demonstrated previously to be the case[4]), and that it is influenced less by duration of anaesthesia.[5] In order to test the latter prediction, we conducted a randomized, controlled study to examine the correlations between duration of anaesthesia and emergence times in patients anaesthetized with equal MAC xenon, nitrous oxide–sevoflurane or nitrous oxide–isoflurane for various lengths of time.

Patients and methods

The methods were similar to those of our previous investigation[4] with slight modifications.

After written informed consent was obtained, we studied 54 ASA I or II patients of both sexes, aged 32–64 yr, undergoing elective lower abdominal surgery (mainly gynaecological procedures) according to a design approved by the Institutional Human Studies Committee of Teikyo University. Patients with pulmonary, cardiovascular, hepatic, renal or neurological diseases were excluded. Also excluded were patients receiving medications known to influence anaesthetic or analgesic requirements and those who had contraindications to extradural anaesthesia (e.g. coagulopathy, history of allergic reactions to local anaesthetics, patient's refusal). Preanaesthetic laboratory values were within normal limits.

When the unpremedicated patient arrived in the operating theatre, midazolam 30 $\mu g\ kg^{-1}$ was administered i.v. An extradural catheter was placed at the L2–3 interspace, through which 1.5% mepivacaine with adrenaline 1:200 000 were administered, 3 ml as a test dose, followed 3 min later by an additional 9–12 ml depending on the height of the patient. If a sensory level to pinprick of T10 or higher was not obtained within 15 min, the extradural catheter was judged to be functioning inadequately and the patient was excluded from the study. A well-functioning extradural catheter was

Correspondence to T. G.

regarded as an essential component of our anaesthetic technique because of the MAC value of xenon (71%) and our desire to avoid other systemic supplementations while assuring patient comfort.

Patients were allocated randomly to one of three anaesthetic treatment groups: xenon, nitrous oxide–sevoflurane or nitrous oxide–isoflurane ($n=18$ per group). General anaesthesia was induced with fentanyl 2 μg kg^{-1} and thiopentone 4 mg kg^{-1} i.v., and the trachea was intubated with the aid of vecuronium 10 mg i.v. Patients were then denitrogenated for 30 min using an inflow of oxygen 8 litre min^{-1} in order to suppress nitrogen accumulation within the system during subsequent closed-circuit anaesthesia.[6] During this denitrogenation period, anaesthesia was maintained with 1% isoflurane (xenon and nitrous oxide–isoflurane groups) or 1.8% sevoflurane (nitrous oxide–sevoflurane group). The end-tidal concentration of carbon dioxide (E'_{CO_2}) was maintained at 4.0–4.7 kPa with mechanical ventilation. If clinically indicated, adrenaline 4–8 mg or phenylephrine 50–100 μg were administered i.v. to maintain systemic arterial pressure at acceptable levels.

Routine monitoring devices included an oesophageal stethoscope with a temperature sensor, ECG (lead II), automated arterial pressure cuff and pulse oximeter. End-tidal concentrations of nitrous oxide, carbon dioxide, sevoflurane and isoflurane were monitored continuously with an infrared gas analyser (PM 8050, Drägerwerk, Lübeck, Germany). The end-tidal concentration of xenon was monitored continuously using a xenon analyser (Anzai Medical, Tokyo, Japan), which was calibrated before each case with the use of an 80% xenon–20% oxygen mixture analysed to ±0.02% accuracy (Nihon-Sanso, Tokyo, Japan). The effective working range for this monitor was 1–100% with an error of ±1% and 90% response time of less than 1 s.

Thirty minutes after induction of anaesthesia when denitrogenation was complete, xenon, nitrous oxide–isoflurane or nitrous oxide–sevoflurane was started. For the xenon patients, oxygen was stopped and the upright ventilator bellows was deflated completely and refilled quickly with 100% xenon. Xenon was then started at 2 litre min^{-1}. Two to three minutes later when the end-tidal concentration reached 60%, xenon flow was reduced, oxygen was resumed and the anaesthesia system was closed in order to minimize subsequent expenditure of xenon. During closed-circuit anaesthesia, fresh inflow rates of xenon and oxygen were adjusted to maintain the end-tidal concentration of xenon at 60%. Xenon inflow was recorded every minute in seven patients for whom the anaesthesia system was made highly leak-free (leak <30 ml min^{-1} at a constant circuit pressure of 20 cm H_2O). When the end-tidal oxygen concentration decreased to less than 20% because of accumulation of nitrogen, the system was flushed with a 60% xenon–40% oxygen mixture. Although no additional volatile anaesthetic was administered after xenon was started, our pilot study revealed that 0.1–0.2% isoflurane was always detected in the system, presumably because the isoflurane vapour contained within the patient's lungs at the time of circuit closure was retained in the breathing system. Therefore, it was estimated that patients in the xenon group were receiving approximately 0.9 MAC of anaesthesia, assuming additivity of MAC, because xenon and isoflurane provided $60/71=0.84$ and $0.1/1.15=0.085$ MAC, respectively. In order to provide the same MAC fractions in the nitrous oxide–sevoflurane and nitrous oxide–isoflurane groups, end-tidal concentrations of nitrous oxide, sevoflurane and isoflurane were maintained at 60%, 0.7% and 0.5%, respectively.[3 7] The total inflow of 3 litre min^{-1} was used in the nitrous oxide–volatile anaesthetic groups.

In addition, all patients received continuous extradural infusion of 1.5% mepivacaine containing adrenaline 1:200 000 at 6 ml h^{-1}, started immediately after induction of anaesthesia. When xenon or nitrous oxide was started, the extradural infusion rate was adjusted to maintain mean arterial pressure and heart rate within 20% of preoperative values. Additional doses of vecuronium or pancuronium were administered if indicated clinically. Body temperature was maintained with the use of a warming mattress placed on the operating table. I.v. fluids were also warmed.

Before skin closure, residual neuromuscular block was antagonized by neostigmine 2.5 mg and atropine 1.0 mg i.v., and spontaneous ventilation was allowed to return. At the end of operation, all inhalation anaesthetics were discontinued and oxygen 8 litre min^{-1} was administered. E'_{CO_2}, ventilatory frequency and oesophageal temperature were recorded at this time. An investigator who was blinded to the anaesthetic regimen administered recorded the times from discontinuation of the anaesthetics until patients opened their eyes on verbal command and were judged ready for extubation (i.e. in addition to opening eyes, they either squeezed the investigator's hand or took a deep breath on command and showed a regular breathing pattern). Furthermore, times when patients regained orientation, that is when they were able to correctly state their name, date of birth and name of the hospital, were recorded. Finally, times when patients could count backwards from 10 to 1 in less than 15 s were recorded. These emergence times were assessed at either 30-s (eye opening and extubation) or 60-s (orientation and counting backward) intervals. Fifteen minutes after tracheal extubation when the continuous extradural infusion was stopped, extradural block level to pinprick was examined, and patients were asked to rate their incisional pain using a 0–10 verbal rating scale, with 0 and 10 being no pain and the worst pain imaginable, respectively. The incidence of nausea or vomiting during the first 1 h after extubation was also recorded, and antiemetics (e.g. metoclopramide 10 mg i.v.) were administered as necessary. All patients were asked 24 h after operation if they had recall of intraoperative events.

STATISTICAL ANALYSIS

To evaluate the correlations between duration of anaesthesia and each emergence time, a regression line was constructed by the least squares method for each anaesthetic regimen. Because no significant correlation was found for the xenon and nitrous oxide–sevoflurane groups, they were compared with respect to each emergence time using an unpaired *t* test. Data (except duration of anaesthesia, pain rating, extradural analgesia level and incidence of nausea/vomiting) are reported as mean (SD) and were analysed using analysis of variance (ANOVA) followed by Dunnett's *t* tests with the xenon group as a control. The incidence of postoperative nausea/vomiting was analysed using a chi-square test. The remainder are expressed as median (range) and were analysed using the Kruskal–Wallis test with Mann–Whitney *U* tests used to assess differences between the xenon and other groups. $P<0.05$ was considered statistically significant.

Results

The three groups were comparable in age, height and weight (table 1). Duration of anaesthesia after the start of xenon or nitrous oxide anaesthesia was 58–380 min and did not differ between groups (table 1).

The rates of recovery from xenon and nitrous oxide–sevoflurane anaesthesia to four different end-points did not correlate with duration of anaesthesia, whereas those from nitrous oxide–isoflurane anaesthesia did (fig. 1A–D). Mean emergence times from xenon *vs* nitrous oxide–sevoflurane were: 3.3 (1.0) *vs* 5.6 (1.4) min to opening eyes; 3.6 (1.0) *vs* 6.3 (1.0)

Table 1 Patient data (mean (SD or range) or median[range])

	Xenon	N_2O–sevoflurane	N_2O–sevoflurane
Age (yr)	44 (33–58)	45 (32–64)	43 (34–56)
Height (cm)	158 (7)	156 (7)	157 (8)
Weight (kg)	58 (7)	56 (8)	56 (10)
No. of males	3	2	2
Duration of anaesthesia (min)	162 [58–380]	144 [58–303]	127 [61–296]

Table 2 Postoperative data. End-tidal carbon dioxide concentrations (E'_{CO_2}), ventilatory frequency and oesophageal temperature (temp.) were measured at the end of operation. Extradural dose=total volume of 1.5% mepivacaine with adrenaline 1:200 000 administered extradurally until 15 min after extubation. Pain rating=numerical quantification of incisional pain by the patient using a 0–10 verbal rating scale, with 0 and 10 being no pain and worst pain imaginable, respectively. Data are reported as mean (SD) or median [range]

	Xenon	N_2O–sevoflurane	N_2O–sevoflurane
E'_{CO_2} (kPa)	5.6 (0.5)	5.6 (0.7)	5.9 (0.5)
Ventilatory frequency (bpm)	21 (4)	23 (5)	20 (5)
Oesophageal temp (°C)	36.0 (0.2)	35.8 (0.2)	35.9 (0.3)
Extradural mepivacaine dose (ml)	36 (16)	32 (13)	31 (14)
Extradural analgesia level	T8 [T6–10]	T9 [T6–10]	T9 [T7–11]
Pain rating	3 [0–5]	2 [0–4]	2 [0–5]
Nausea/vomiting	9	7	6

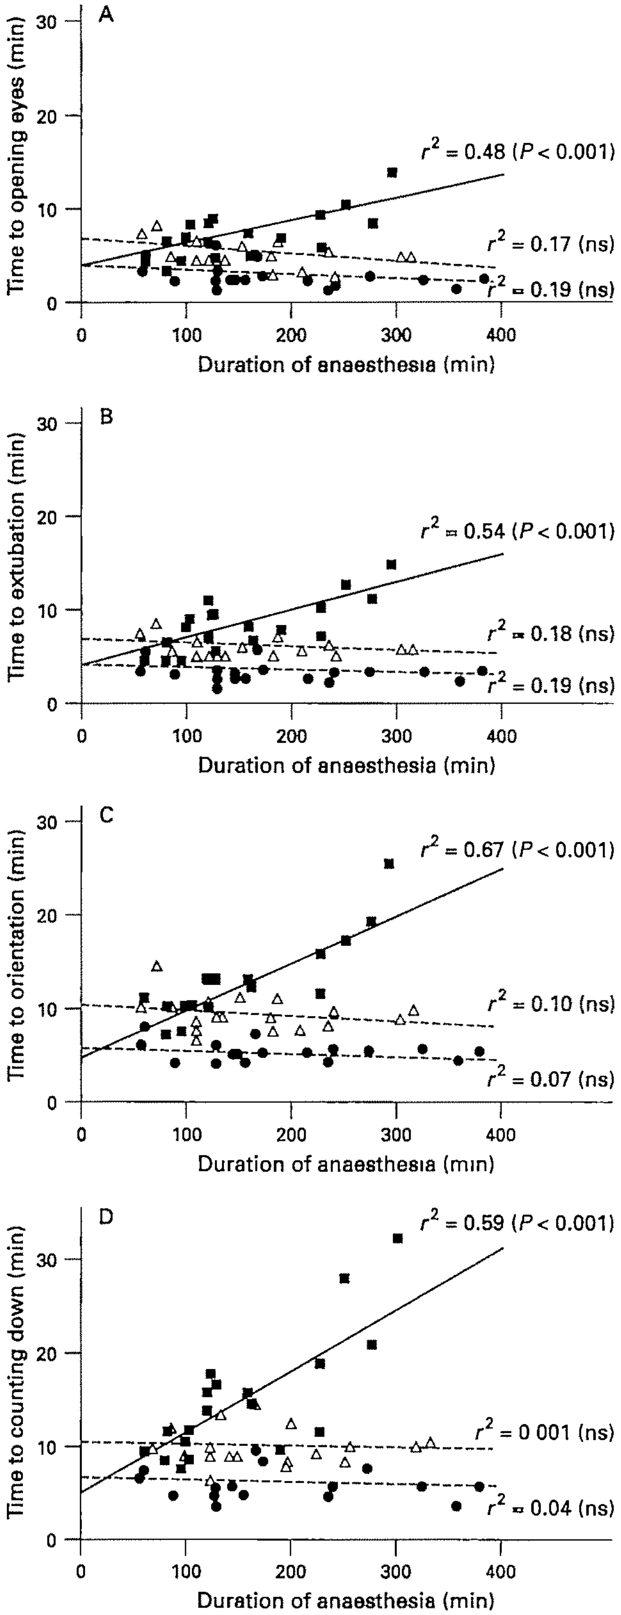

Figure 1 Correlations between duration of anaesthesia and emergence times from anaesthesia after xenon (●), nitrous oxide–sevoflurane (△) or nitrous oxide–isoflurane anaethesia (■) to four different end-points: from discontinuation of anaesthetic until patients could (A) open their eyes, (B) had their tracheas extubated, (C) state their name, date of birth and name of the hospital correctly (orientation), and (D) count backwards from 10 to 1 in less than 15 s. Each regression line was constructed by the least squares method. Whereas emergence times from nitrous oxide–isoflurane were correlated linearly with duration of anaesthesia ($P<0.001$), there was no significant correlation for xenon and nitrous oxide–sevoflurane, indicated by the broken regression lines.

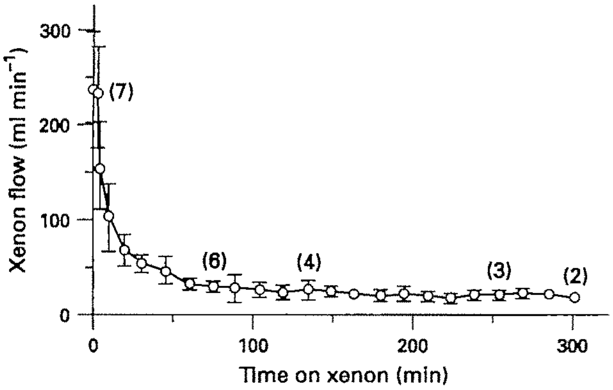

Figure 2 Inflow rate of xenon during closed-circuit anaesthesia. Data are mean (SD) for the number of patients indicated (parentheses). The least squares method revealed that (xenon inflow in ml min^{-1})$^{-1}$=0.005((time on xenon in min)$^{1/2}$ -1), r^2=0.75 (P<0.001).

min to tracheal extubation; 5.0 (1.1) *vs* 9.3 (1.8) min to regaining orientation; and 6.2 (1.7) *vs* 10.5 (2.0) min to counting down (all P<0.01).

The final end-tidal concentration of isoflurane in the xenon group was 0.1%. There was no difference in postoperative oesophageal temperature, E'_{CO_2}, ventilatory frequency, extradural analgesia level, pain rating or total amount of extradural mepivacaine administered (table 2). The incidence of postoperative nausea or vomiting was also comparable between groups (table 2). No subject experienced intraoperative awareness or other major anaesthesia-related adverse events.

The inflow rate of xenon after the system was closed declined exponentially from 229 (57) ml min^{-1} at 3 min to 33 (5) ml min^{-1} at 60 min and to <30 ml min^{-1} after 120 min (fig. 2). Expenditure of xenon between 3–60, 60–120, 120–180 and 180–240 min was 3819 (420) ml (n=7), 1721 (537) ml (n=6), 1358 (350) ml (n=4) and 943 (300) ml (n=4), respectively, excluding gas used to flush the anaesthesia system.

Discussion

We have demonstrated that xenon was associated with fast emergence from anaesthesia, regardless of duration. This was also the case with nitrous oxide–sevoflurane, although emergence times were approximately twice as long as those after xenon. In contrast, duration of anaesthesia had a significant impact on recovery from nitrous oxide–isoflurane. It was prolonged markedly after a long anaesthetic but was only slightly slower than that after xenon with a brief anaesthetic. The results are consistent with the widely accepted concept that lower blood:gas partition coefficients render emergence less dependent on duration of anaesthesia because of less accumulation of anaesthetic in body tissues.[5] This concept, however, assumes that the MAC fractions required to achieve each end-point of emergence are similar for different anaesthetics, although this assumption has been questioned recently[8] and xenon has never been compared with other agents in this regard. Other factors potentially influencing the rate of emergence such as age, sex, body temperature, pain and amount of supplementary anaesthetics and analgesics administered (including extradural local anaesthetic) did not differ between the three anaesthetic groups. Minute ventilation was also probably comparable because the end-tidal carbon dioxide concentration and ventilatory frequency at the end of operation were similar.

Our results also suggest that the quality of emergence after prolonged anaesthetics might be different between xenon and other inhalation agents, especially nitrous oxide–isoflurane. For example, when anaesthetics lasting more than 3 h are considered, all six patients who received xenon were oriented and able to count backwards by 5 and 8 min, respectively, whereas four of six patients anaesthetized with nitrous oxide–isoflurane were unable to open their eyes by 8 min. In accordance with this, patients in the xenon group in general appeared less sedated and more clear-headed in the post-anaesthesia period. Although it remains to be determined whether or not these characteristics lead to earlier "ward-readiness", xenon appears to have significant clinical potential in the setting where rapid, clear emergence is important.

The inflow rate of xenon required to conduct closed-circuit anaesthesia, which theoretically equals uptake by a patient, declined exponentially with time and followed a similar temporal pattern as those of other inhalation anaesthetics.[9] This has profound economical implications when expensive agents such as xenon are used, because the mean hourly expenditure, and hence cost, would be progressively lower with more prolonged anaesthetics. In this study, 2-, 3- and 4-h anaesthetics required approximately 10, 11.4, and 12.3 litre of xenon, including that used to initially increase the end-tidal concentration to 60%. The respective acquisition costs were approximately UK£80.00, £91.20 and £98.4, respectively (xenon costs UK£8.00 per litre in Japan). In comparison, nitrous oxide–isoflurane and nitrous oxide–sevoflurane anaesthesia with a total inflow of 3 litre min^{-1} cost UK£28.50 and £30.00 for 2 h, £42.75 and £45.00 for 3 h, and £57.00 and £60.00 for 4 h, respectively. (The prices of isoflurane and sevoflurane in Japan are the same, UK£0.50 per ml of liquid agent. Nitrous oxide costs UK£0.10 per litre of gas.) Thus the differences in cost between xenon and nitrous oxide–volatile anaesthetic combinations become smaller with a longer duration of administration. It could be reduced further by using the circuit priming method described elsewhere[10] instead of using high flow for the first 3 min as we did in this study. At the current price, however, xenon anaesthesia is still expensive. Whether or not the potential benefits of xenon, such as rapid recovery as demonstrated in this study, are sufficient to merit the increased costs remains to be determined.

In summary, we have demonstrated that xenon was associated with rapid emergence from anaesthesia, regardless of duration, which is consistent with its low blood:gas partition coefficient. In addition, uptake rate declined exponentially over time to less than 30 ml min^{-1} after 2 h of anaesthesia. These properties, together with its inert nature predicting low toxicity, would make xenon a favourable choice for prolonged anaesthesia. Further evaluation of its clinical characteristics and a cost–benefit ratio are warranted to determine if this "close-to-ideal" anaesthetic gas[11] can be adopted in clinical practice.

Effect of systemic N-methyl-D-aspartate receptor antagonist (dextromethorphan) on primary and secondary hyperalgesia in humans

S. ILKJÆR, J. DIRKS, J. BRENNUM, M. WERNBERG AND J. B. DAHL

Summary

Dextromethorphan is a non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist known to inhibit wind-up and central hyperexcitability of dorsal horn neurones. We studied 24 healthy, unmedicated male volunteers, aged 21–28 yr, in a randomized, double-blind, placebo-controlled, crossover study. Burn injuries were produced on the medial surface of the dominant calf with a 25×50 mm rectangular thermode. On three separate days, at least 1 week apart, subjects were given oral dextromethorphan 60 mg, 120 mg or placebo. Dextromethorphan reduced the magnitude of secondary hyperalgesia to pinprick but not to stroke. Dextromethorphan had no influence on primary hyperalgesia, pain during prolonged noxious heat stimulation or heat pain detection thresholds in undamaged skin. Side effects were frequent but clinically acceptable. The effects of dextromethorphan were in agreement with experimental studies indicating that dextromethorphan is a NMDA receptor antagonist. The effects of dextromethorphan in the burn injury model were similar to those of ketamine and distinct from those of local anaesthetics and opioids. (*Br. J. Anaesth.* 1997; **79**: 600–605).

Key words
Pharmacology, dextromethorphan. Pain, mechanism. Pain, postoperative. Model, burn injury.

Over the past several years, evidence has accumulated that peripheral tissue injury may lead to hyperexcitability of wide dynamic range (WDR) neurones in the dorsal horn. Prolonged C-afferent activity evokes wind-up, a state that results in increased receptive fields and exaggerated responses of the WDR neurones to afferent input.[1] Wind-up can augment responses of dorsal horn neurones up to 20-fold in magnitude and duration. This state of hyperexcitability may even continue after cessation of the peripheral input.[2] Central sensitization induces altered processing of afferent activity evoked by both innocuous and noxious stimuli. Clinically this is manifested as allodynia (pain caused by a stimulus that does not normally provoke pain) and hyperalgesia (increased response to a stimulus that is normally painful).[3] Injury-induced sensitization of dorsal horn neurones has been implicated as an important contributor to both acute and chronic pain states.[4]

Experimental studies have indicated that the N-methyl-D-aspartate (NMDA) receptor plays a significant role in wind-up and spinal hyperexcitability.[5 6] Both animal and human studies have shown that NMDA antagonists can reduce spinal hyperexcitability, leading to renewed interest in NMDA receptor antagonists such as ketamine and dextromethorphan.[7–11]

Dextromethorphan has been used as an antitussive agent for more than 30 yr. Since its development, little attention has been directed towards the CNS pharmacology of this drug. The discovery of high affinity binding sites for dextromethorphan in the brain and possible anticonvulsant, neuroprotectant, anti-ischaemic and anti-pain properties has lead to an increased interest in the drug.[12] Both dextromethorphan and its metabolite dextrorphan appear to be NMDA receptor antagonists.[13 14] Experimental studies indicated that dextromethorphan reduced NMDA-mediated nociceptive responses in the dorsal horn neurones[13–15] and a reduction in wind-up has been indicated in a clinical study.[10] It has been reported that the side effects of dextromethorphan are rare and mostly unimportant, and that the drug has a wide margin of safety.[16]

Cutaneous heat injury evokes allodynia and hyperalgesia for mechanical and heat stimuli within the injured area (primary hyperalgesia) and allodynia for mechanical, but not heat, stimuli in an area surrounding the injury (secondary hyperalgesia).[17] There is convincing evidence that secondary hyperalgesia is a result of altered central processing of afferent activity because of sensitization of dorsal horn neurones, whereas primary hyperalgesia seems to be caused by a combination of sensitization of

Correspondence to S. I.

peripheral receptors and central neurones.[9 18–22] The burn injury model has been used previously to study the effects of various analgesics in human volunteers.[9 23 24]

The aim of the study was to investigate the effects of oral dextromethorphan on pain and hyperalgesia after a burn injury in human volunteers.

Subjects and methods

We studied 25 healthy, unmedicated male volunteers, mean age 24 (21–28) yr, after obtaining informed consent and approval from the regional Ethics Committee and the Danish National Health Board. One subject was excluded because of incorrect medication on one examination day. The study was performed in a quiet room with subjects in a semi-supine position. Each subject had been familiarized with the burn injury and measurement procedures on a separate day.

HYPERALGESIA

Burn injuries were produced on the medial surface of the dominant calf (L3–4 dermatome) with a 25×50 mm rectangular thermode (Thermotest, Somedic A/B Sweden) applied to the skin with a standardized pressure (8 kPa). The temperature of the thermode was 47 °C and application time was 7 min. This resulted in a first-degree burn injury, that is redness without blistering.

Pain ratings were performed continuously by the volunteer by moving a lever that controlled a vertical bar on a computer screen (sample rate 2 Hz). The visual analogue score (VAS) was anchored with the descriptors "no pain" (numerical value=0) and "worst possible pain" (numerical value=100). The interpretation of "pain" was left to the subject, who was instructed to apply the same interpretation throughout the study.

Brief conditioning was produced with the same thermode placed on the centre of the anterior side of the thigh at 45 °C.[9] After 3 min of heating, the border of hyperalgesia to pinprick and stroke stimuli was determined along four linear paths arranged radially around the thermal injury (see below). Immediately after these determinations the thermode was removed. These brief conditioning stimuli induced slight or no pain during heating and no spontaneous sensations after termination. The mechanical hyperalgesia induced by these brief conditioning stimuli never lasted more than a few minutes beyond the duration of the conditioning stimuli.

MEASUREMENT OF MECHANICAL HYPERALGESIA

The temperature of the injured site was stabilized at 35 °C, with the above described thermode, from 1 min before and throughout assessment of mechanical hyperalgesia. The border of hyperalgesia to pinprick and stroke stimuli was determined by stimulating along four linear paths arranged radially around the thermal injury in steps of 5 mm at intervals of 1 s, starting well outside the hyperalgesic area where neither stimulus type evoked pain. Stimulations continued towards the injury until subjects reported a clear change in sensations ("burning", "tenderness", "more intense pricking"). The areas of hyperalgesia were calculated using a vector algorithm.[23] Pinprick was performed with the von Frey technique using a nylon filament with a diameter of 1 mm and a bending force of 1.15 N. Stroke stimulation was performed by lightly stroking the skin with a gauze swab.

MEASUREMENT OF THERMAL THRESHOLDS

Heat pain detection threshold (HPDT) was defined as the lowest temperature percived as painful. The thermode was identical to that used for production of the burn injury. HPDT was determined from a baseline temperature of 32 °C with a rate of change of 1 °C s^{-1}. By pressing a button, subjects indicated when the pertinent threshold was reached. This value was recorded and the stimulator returned to baseline. If the cut-off limit (52 °C) was reached before the pertinent threshold, the thermode returned automatically to baseline and a threshold of 52 °C was registrered (it did not happen in any of the threshold measurements). Each threshold was calculated as the average of three measurements with randomized intervals (6–10 s) between each stimulation. Thermal thresholds were determined at the site of injury and at the corresponding site of the contralateral, unburned calf.

Table 1 Experimental design

Time	Actions/measurements
Baselines	Area of secondary hyperalgesia to pinprick and stroke during brief conditioning, thigh.
	Heat pain detection threshold (HPDT), right and left calf
0 min	Oral dextromethorphan 60 mg, 120 mg or placebo
105–115 min	Side effects
	Area of secondary hyperalgesia to pinprick and stroke during brief conditioning, thigh
	HPDT, right and left calf
120–127 min	Burn injury, right calf; measurement of pain with electronic VAS during burn
180–200 min	Side effects
	Area of secondary hyperalgesia to pinprick and stroke during brief conditioning, thigh
	HPDT, right and left calf
	Area of secondary hyperalgesia to pinprick and stroke around burn injury, right calf
240–260 min	Side effects
	Area of secondary hyperalgesia to pinprick and stroke during brief conditioning, thigh
	HPDT, right and left calf
	Area of secondary hyperalgesia to pin prick and stroke around burn injury, right calf

ASSESSMENT OF SIDE EFFECTS

Drowsiness was assessed on an 11-point analogue scale (0=completely awake; 10=almost asleep). Discomfort was assessed on an 11-point analogue scale (0=no discomfort; 10=maximum discomfort). Dizziness was assesed on an 11-point analogue scale (0=no dizziness, 10=maximum dizziness). Nausea was registered as four graduations (none, light, moderate or severe). Finally, subjects were asked if they experienced other sensations.

EXPERIMENTAL PROCEDURE

On three separate days, at least 1 week apart, subjects received oral dextromethorphan 60 mg, 120 mg or placebo, 2 h before induction of hyperalgesia. The study was double-blind and the order of treatments was randomized. Timing of the various assessments is shown in table 1.

STATISTICAL ANALYSIS

Data are presented as median (lower and upper quartiles). Variables were evaluated with Wilcoxon's test for paired data. All significant *P* values were corrected with Bonferroni's test for repeated measurements. $P<0.05$ was considered statistically significant.

Results

CONTROL (PLACEBO) DAY

Pain during burn injury increased rapidly during the first 15–30 s, reached a plateau and then remained relatively stable during the remaining 6 min (fig. 1).

After induction of injury, no spontaneous pain or other sensations were experienced from the site of injury.

The borders of secondary hyperalgesia for pinprick and stroke stimuli surrounding the burn injury on the calf (table 2) and the area of secondary hyperalgesia for pinprick and stroke stimuli evoked by brief conditioning on the thigh (table 3) were detected easily in all subjects.

HPDT inside the burned area decreased from a baseline value of 47.6 (47.0–48.8) °C to 44.4 (43.6–45.8) °C, 60 min after the injury, and remained decreased throughout the study ($P<0.05$) (table 4). HPDT on the contralateral calf did not change throughout the study ($P>0.05$) (table 4).

EFFECTS OF DEXTROMETHORPHAN

There were no differences in pain ratings during

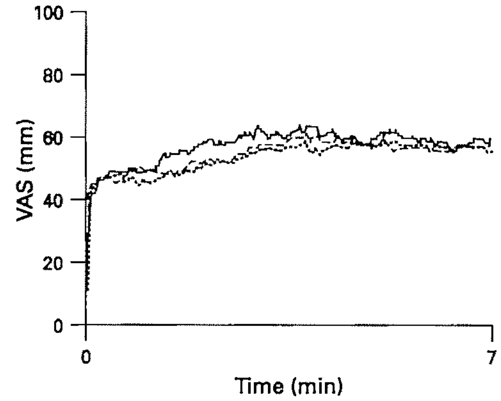

Figure 1 Median pain scores (VAS) during burn injury after treatment with dextromethorphan 120 mg (–), 60 mg (....) and placebo (–––) (ns, Wilcoxon rank test).

Table 2 Area of secondary hyperalgesia to pinprick and stroke stimuli (cm^2) around the burn injury during treatment with dextromethorphan 120 mg, 60 mg and placebo (medians (lower and upper quartiles)). *$P<0.05$ compared with placebo

induction of the burn injury between dextromethorphan 120 mg, 60 mg or placebo (fig. 1) (120 mg *vs* placebo, $P=0.60$; 60 mg *vs* placebo, $P=0.98$ (Wilcoxon rank test)).

MEASUREMENT OF MECHANICAL HYPERALGESIA

At the burn injury (calf) the areas of secondary hyperalgesia to pinprick but not to stroke were reduced by dextromethorphan 120 mg compared with placebo at 180 min after administration of the drug ($P<0.008$, corrected for multiple comparisons (pinprick), $P=0.07$ (stroke)). There was no difference in the areas at 240 min ($P=0.10$ (pinprick), $P=0.74$ (stroke)) (table 2).

Dextromethorphan 60 mg had no influence on the area of secondary hyperalgesia for pinprick ($P=0.24$, $P=0.51$) or for stroke ($P=0.29$, $P=0.08$) at 180 min or 240 min after administration of the drug, respectively (table 2).

On the thigh, the area of secondary hyperalgesia to pinprick but not to stroke was reduced by dextromethorphan 120 mg compared with placebo at 180 min but not at 240 min after drug administration ($P=0.048$, corrected for multiple comparisons). No significant effects were observed with dextromethorphan 60 mg (table 3).

MEASUREMENT OF THERMAL THRESHOLDS

At the site of injury there was no difference in the decrease in HPDT between dextromethorphan 120 mg, dextromethorphan 60 mg or placebo treatment (dextromethorphan 120 mg *vs* placebo, $P>0.1$; dextromethorphan 60 mg *vs* placebo, $P>0.2$). Hence, dextromethorphan in these doses did not influence primary hyperalgesia (table 4).

At the contralateral uninjured calf there was no difference in HPDT between dextromethorphan 120 mg, dextromethorphan 60 mg or placebo treatment (dextromethorphan 120 mg *vs* placebo, $P>0.07$; dextromethorphan 60 mg *vs* placebo, $P>0.1$). Hence dextromethorphan had no influence on HPDT in non-injured skin (table 4).

SIDE EFFECTS

Dizziness was more pronounced with dextromethorphan 120 mg, but not with 60 mg, compared with placebo ($P<0.05$) (range 1–5 on the analogue scale). The difference was significant at 105 and 180 min, but not at 240 min after administration. Only a few subjects experienced slight nausea, drowsiness and discomfort, but these adverse effects were observed also in the placebo group. In general, the frequency of side effects was low, and after 240 min they had almost disappeared. No volunteer wished to leave or was excluded from the study because of side effects. All volunteers were able to collaborate fully during the various assessments without problems.

Discussion

In this study we found dextromethorphan to have a slight but statistically significant inhibitory effect on mechanical allodynia for pinprick in the area of secondary hyperalgesia after a burn injury in humans. There was no effect on heat pain detection thresholds in normal or injured skin, on mechanical allodynia for stroke in the area of secondary hyperalgesia or on pain evoked by prolonged heat stimuli.

NMDA receptor antagonists differ from "classic" analgesics in their mechanisms of action. They have no effect on the initial nociceptive input, as do opioids or local anaesthetics, but they reduce wind-up and injury-induced facilitation of nociceptive neurones in the CNS. Thus these drugs are expected to exert their analgesic effects only under conditions where tissue damage (e.g. burn injury) or repetitive C-fibre stimulation has induced hyperexcitability of dorsal horn neurones.[2]

Experimental studies have shown that dextromethorphan can reduce wind-up,[13] formalin-induced increases in spinal cord *c-fos* mRNA[15] and pain behaviour.[14 15] Furthermore, dextromethorphan attenuates analgesic tolerance to morphine,[25 26] and it possesses additive analgesic effects when combined with NSAID.[27]

Human studies on dextromethorphan and pain have shown controversial results.[10 11 28–30] In a double-blind, randomized, placebo-controlled crossover design where six volunteers were given oral doses of dextromethorphan 15, 30 or 45 mg, or placebo, Price and colleagues found that dextromethorphan reduced slow temporal summation of electrically and thermally evoked second pain (a correlate with wind-up) in a dose-dependent manner.[10] In another study, oral dextromethorphan 100 and 200 mg did not attenuate pain produced by topical capsaicin or ischaemia 45 min after oral administration, but side effects were pronounced with the higher dose.[30] Wind-up, hyperalgesia or other correlates with central neuronal alterations were not evaluated specifically.[30] Thus it is uncertain if central hyperexcitability had been induced or if effective plasma concentrations were achieved at the time of assessment.[30]

One preliminary clinical study has evaluated the analgesic effect of dextromethorphan after oral surgery. Doses of 60 and 120 mg were given before and every 6 h after operation, and pain was evaluated for 48 h after surgery. Dextromethorphan produced a weak analgesic effect 6 h after operation.[28] Furthermore, in a double-blind, randomized, crossover study, small doses of dextromethorphan (13.5 and 27 mg three times a day) had no effect on neuropathic pain.[29]

Dextromethorphan 60 or 90 mg qid or up to 10 mg kg^{-1} day^{-1}, with total doses in the range 4.8–10 mg kg^{-1} day^{-1}, respectively, have been administered to patients with either a history of transient ischaemic attacks or with amyotrophic lateral sclerosis, with minor but dose-limiting side effects.[31 32]

In this study doses of oral dextromethorphan 60 and 120 mg were chosen because of the lack of analgesic effect with smaller doses in a previous clinical study,[29] the relatively minor side effects observed with higher doses in neurological patients[31 32] and the unacceptable side effects observed with 200 mg in a study in human volunteers.[30] The burn injury was induced 2 h after administration of dextromethorphan as plasma concentrations have been found to be at their maximum 2 h (range 1–4 h) after oral intake.[32] Dextromethorphan reduced secondary hyperalgesia surrounding a first-degree burn injury, and secondary hyperalgesia during short lasting thermal conditioning of the skin. These findings, together with the lack of effect on heat pain detection thresholds in unburned skin, are consistent with previous experimental results[13 15] and with the observations of Price and colleagues.[10] They confirmed that dextromethorphan may reduce injury-induced alterations in dorsal horn neurones without any effect on nociceptive input *per se*. The reduction was significant for pinprick but not for stroke hyperalgesia 3 h after administration of the drug. Taking the side effects into account this could be the period with the highest plasma concentration of the drug; 4 h after drug administration, side effects were reduced and the reduction in secondary hyperalgesia compared with placebo had disappeared.

Cervero and colleagues examined the appearance of secondary hyperalgesia to pinprick and stroke after non-painful heat stimuli.[33] They found that the area of pinprick developed first, followed by flare and hyperalgesia for stroke. This indicates that hyperalgesia to pinprick and stroke may be mediated by different mechanisms.[33] In a recent study, ketamine reduced hyperalgesia for both pinprick and stroke because of a burn injury,[9] while in another study capsaicin-induced hyperalgesia for pinprick, but not for stroke, was reduced by ketamine.[11] This indicates that secondary hyperalgesia for punctuate stimuli are attenuated more by NMDA antagonists than secondary hyperalgesia for stroke. Pain during induction of the burn injury, and heat pain detection thresholds in burned skin, were not influenced by dextromethorphan in contrast with the findings for ketamine.[9] One explanation for this discrepancy could be that in our study dextromethorphan had not reached an adequate plasma concentration during induction of the burn injury but may also reveal differences in potency or mechanisms of action between the two drugs.

Although dextromethorphan induced (insignificant) drowsiness at both doses, heat pain detection thresholds in both healthy and injured skin were unaffected by dextromethorphan. This indicates that the reduction in secondary hyperalgesia with dextromethorphan 120 mg was not caused by side effects.

Our study is in accordance with previous findings and confirms that dextromethorphan may reduce injury-induced alterations in dorsal horn neurones without any effect on nociceptive input *per se*. In experimental studies the combination of NSAID and dextromethorphan was found to have additive analgesic effects and the combination with morphine reduced the development of tolerance.[25–27] Human studies have not yet been performed. Our study provides a rationale for further studies of the effects of dextromethorphan in combination with other analgesics on clinical pain states, such as postoperative pain.

Comparison of perioperative ketoprofen 2.0 mg kg^{-1} with 0.5 mg kg^{-1} i.v. in small children during adenoidectomy

E. NIKANNE, H. KOKKI AND K. TUOVINEN

Summary

We have investigated if ketoprofen 0.5 mg kg^{-1} i.v. provided as good analgesia with less adverse effects compared with ketoprofen 2.0 mg kg^{-1} i.v. in 107 children, aged 1–7 yr, after adenoidectomy, in a randomized, double-blind, parallel group study design. A standard anaesthetic method was used and all children received fentanyl 1 μg kg^{-1} i.v. during induction. Children in group 2.0 received ketoprofen 2.0 mg kg^{-1} and children in group 0.5, 0.5 mg kg^{-1} i.v. during induction. If the child was in pain, fentanyl 1 μg kg^{-1} was given i.v. as rescue analgesia. We found that ketoprofen provided good analgesia and only 49% of children required fentanyl in the post-anaesthesia care unit. There were no differences between the groups in the number of fentanyl doses, pain scores or frequency of adverse reactions. No serious adverse reactions occurred. (*Br. J. Anaesth.* 1997; **79**: 606–608).

Key words
Analgesia, pre-emptive. Analgesics non-opioid, ketoprofen. Children. Anaesthesia, day-case. Surgery, otolaryngological.

Postoperative pain is frequent in children, even after minor surgery. After myringotomy alone, more than 40%[1] and after adenoidectomy at least 80% of children need analgesic treatment.[2]

Adenoidectomy is performed frequently as a day-case operation and in most cases the patients are small children. It is important to find an effective and safe analgesic treatment for these patients. Opioids have been used because of their good analgesic effects, although adverse effects include emesis, excessive sedation and the risk of respiratory depression.

Non-steroidal anti-inflammatory drugs (NSAID) have been used for pain treatment in day-case surgery for mild and moderate pain and as a background analgesic for severe pain with good results.[3] They also have known adverse effects such as gastrointestinal and renal dysfunction. NSAID increase perioperative bleeding by inhibiting cyclo-oxygenase and this leads to a prolonged bleeding time by inhibition of platelet thromboxane A_2 production and platelet aggregation. Inhibition of cyclo-oxygenase depends on the blood concentration of the drug.[4] Because these adverse effects are dose dependent it is important to find the smallest effective dose of the drug.

Ketoprofen is a NSAID with the chemical composition of 2-(3-benzophenyl)-propionic acid.[5] It is available in i.v., i.m., oral and rectal formulations. In our previous study we showed that perioperative i.v. ketoprofen had a good analgesic effect in a dose of 2 mg kg^{-1} during adenoidectomy.[6] Ketoprofen has been recommended for administration in a dose of 2.5 mg kg^{-1} for acute pain in children.[4] In an oral dose of 0.5 mg kg^{-1}, ketoprofen has been shown to have a good antipyretic effect.[7]

The aim of this study was to see if ketoprofen 0.5 mg kg^{-1} i.v. provided as good analgesia with less adverse effects compared with ketoprofen 2.0 mg kg^{-1} i.v. in children aged 1–7 yr after adenoidectomy.

Patients and methods

The study was approved by the Ethics Committee of Kuopio University Hospital and the parents of patients gave written informed consent. We studied 107 ASA I patients, aged 1–7 yr, undergoing adenoidectomy. Patients were excluded if they had a known allergy to ketoprofen or other NSAID, asthma, kidney or liver dysfunction, or haemorrhagic diathesis. A randomized, double-blind, parallel group study design was used. Children were allocated randomly to either group 2.0 (ketoprofen 2.0 mg kg^{-1}) ($n=54$) or group 0.5 (ketoprofen 0.5 mg kg^{-1}) ($n=53$).

A standard anaesthetic technique was used. Each child was premedicated with diazepam 0.5 mg kg^{-1} orally up to a maximum of 10 mg, 30–45 min before induction of anaesthesia. EMLA cream (Astra, Sweden) was applied to the skin 60 min before venepuncture. Anaesthesia was induced with thiopentone 5–7 mg kg^{-1} and fentanyl 1 μg kg^{-1} i.v. and tracheal intubation was facilitated with atracurium 0.5 mg kg^{-1}. All children received fentanyl 1 μg kg^{-1} i.v. at induction and no more opioid was given during operation.

Correspondence to H. K.

After induction of anaesthesia, children received ketoprofen (Orudis, Rhone-Poulenc-Rorer, Denmark) 2.0 or 0.5 mg kg^{-1} dissolved in 10 ml of 0.9% saline injected i.v. over 10 min. Anaesthesia was maintained with 1–1.2% isoflurane (inspired concentration) and 65% nitrous oxide in oxygen with IPPV. On completion of the procedure, neuromuscular block was antagonized with neostigmine 50 μg kg^{-1} and glycopyrronium 10 μg kg^{-1}.

All children were given 0.9% saline 10 ml kg^{-1} h^{-1} for intraoperative fluid maintenance. After surgery, children were transferred to the post-anaesthesia care unit (PACU) for continuous monitoring of vital signs and assessment of pain.

The adenoids were removed using indirect currettizarion. Haemostasis was controlled with nasopharyngeal packs with or without electrocautery. Surgeons estimated the amount of bleeding using a five-point scale (1="no bleeding", 2="less than normal", 3="normal", 4="more than normal" and 5="profuse").

Postoperative pain was assessed by the Maunuksela score,[8] which is an observer assessment based on facial expression, vocalization, movement or rigidity of the limbs and body, response to handling and irritability, together with measured cardiorespiratory variables. In the modified score, 0="no pain", 1–3="mild pain", 4–6="moderate pain", 7–9="severe pain" and 10="worst possible pain".

Specially trained research nurses assessed the pain expressed by the child at rest and during swallowing. If the child was in pain (pain score at rest was 3 or more) fentanyl 1 μg kg^{-1} was given i.v. for rescue analgesia. The dose was repeated at 5-min intervals until the child was comfortable. No more than three doses of fentanyl were allowed in 1 h. No other analgesic medication was permitted during the study. The children were monitored closely after each dose of fentanyl in the PACU. On leaving hospital, pain was assessed by a specially trained research nurse at rest and during swallowing. All adverse reactions were recorded and summarized for each patient.

Analysis of variables was performed using the two tailed Student's *t*-test and chi-square test. $P<0.05$ was considered statistically significant. Results are presented as number of patients (%) or mean (SD) where appropriate.

Results

Sex distribution, age, weight and type of surgery performed were similar in the two groups (table 1).

There were no differences in the number of fentanyl doses needed in the PACU. In group 2.0, 27 (50%) and in the group 0.5, 25 (47%) children needed supplementary doses of fentanyl. The number of fentanyl doses needed in the PACU was 0.7 (SD 0.8) in both groups.

There were no differences between the groups in the Maunuksela pain scores (table 2).

In the PACU there was no difference in the frequency of adverse reactions between the groups (table 3). In group 2.0, seven (13%) and in the group 0.5, nine (17%) children had one or more adverse reactions. There were no serious adverse reactions but one patient who received ketoprofen 2.0 mg kg^{-1} developed minor urticaria and conjunctivitis.

Table 1 Patient data for the two groups (mean (SD or range) or number)

	Group 2.0 (n=54)	Group 0.5 (n=53)

The surgeon estimated the amount of intraoperative bleeding using a five-point scale. There was no difference between the groups in the amount of bleeding (table 4). One child in group 2.0 had postoperative bleeding and was transferred to the ward. The bleeding stopped without any intervention. He was observed for a few hours before being discharged.

Discussion

We have found that i.v. ketoprofen at a dose 2.0 mg kg^{-1} did not provide better analgesia than a dose of 0.5 mg kg^{-1} in small children during adenoidectomy. The Maunuksela pain scores were at acceptable levels throughout the study in both groups.

In the PACU only 49% of all children needed supplementary doses of i.v. fentanyl and there was no difference between the groups in the need for supplementary analgesia. In 31% of patients, one dose and in 17% of patients, two doses of fentanyl were given. We found that the need for supplementary doses of fentanyl was smaller than expected, possibly because of the analgesic effects of i.v. ketoprofen during operation.

The incidence of adverse reactions was 15%. In previous studies on the use of ketoprofen the incidence varied from 0% to approximately 50% of patients.[5] There were no serious adverse effects in this study but one patient in group 2.0 had an allergic reaction after injection of ketoprofen and developed urticaria and conjunctivitis. The child was treated with an antihistamine, which alleviated his symptoms in a few hours, but he was observed in a ward overnight. The cause of this allergic reaction was possibly ketoprofen. On the other hand, atracurium is known to release histamine and this may have been a possible cause for the urticaria and conjunctivitis. The incidence and scale of adverse reactions in our study were comparable with other reports of short-term use of NSAID in children.[3 9]

Epigastric distress is a known adverse effect of NSAID but did not occur in this study. This may be because of the small dose of ketoprofen used and also because it was administered i.v. Oral ketoprofen may cause epigastric distress by local irritation of the gastric mucosa. In our previous study, one child in the ketoprofen group and one child in the placebo group experienced epigastric distress.[6]

Increased perioperative bleeding has been shown to occur with ketorolac 1 mg kg^{-1}.[10 11] Gunter and colleagues even suggested that ketorolac is contraindicated in children undergoing adenotonsillectomy.[11] In their study ketorolac was used in a dose of 1 mg kg^{-1}. In our opinion this dose is rather excessive because in a previous study a dose of 0.2 mg kg^{-1} had a good analgesic effect after major surgery in children.[9]

We found no difference between the groups in the amount of intraoperative bleeding and none of the children needed further treatment because of bleeding. Only one child in group 2.0 experienced postoperative bleeding. This child was observed for a few hours before discharge. In our previous study, intraoperative bleeding estimated by the surgeon proved to be greater if children received ketoprofen 1 mg kg^{-1} during operation instead of placebo.[6] In that study none of the children experienced bleeding which required intervention or delay in discharge from hospital.

In our opinion, based on this and our previous study,[6] i.v. ketoprofen is a useful analgesic in children undergoing day-case surgery. It provided good analgesia after adenoidectomy in children and we found no major problems with adverse effects or perioperative bleeding. In our two studies, only one of 271 children required an overnight stay in hospital and none needed treatment for bleeding.

Knee–chest *vs* horizontal side position during induction of spinal anaesthesia in patients undergoing lumbar disc surgery

E. LAAKSO, M. PITKÄNEN, J. KYTTÄ AND P. H. ROSENBERG

Summary

In the prone knee–chest position the spread of plain 0.5% bupivacaine in the cerebrospinal fluid and associated haemodynamic changes may be different compared with the horizontal position. A randomized comparison was performed in 40 ASA I–II patients, aged 24–61 yr, undergoing lumbar disc surgery. Subarachnoid injection (27-gauge needle) at the L2–3 interspace with 3 ml of 0.5% bupivacaine was performed with the patient in the operative knee–chest position (prone knee–chest group, *n*=20) or in the horizontal side position (supine side horizontal group, *n*=20). Patients in the supine side horizontal group were turned into the horizontal supine position for 20 min, and subsequently they were placed in the operative knee–chest position. In three patients in the prone knee–chest group, the spinal needle was replaced by a larger needle (25-gauge). The final cephalad extension of sensory analgesia on skin tested by pinprick was T5 (median) in the prone knee–chest group and T6 in the supine side horizontal group. Recovery was also similar, on average 210 min from injection in both groups. The mean decrease in systolic arterial pressure was somewhat greater in the prone knee–chest group (30 mm Hg) than in the supine side horizontal group (13 mm Hg). The need for ephedrine occurred earlier in the supine side horizontal group (three patients, all within 10 min from local anaesthetic injection) than in the prone knee–chest group (six patients, all after 15 min). Four of the latter patients also required administration of an anticholinergic for bradycardia compared with two patients in the supine side horizontal group. Light sedation was given to five patients in the prone knee–chest group and to four in the supine side horizontal group because of numbness and aching in the shoulders. We conclude that spinal block was similar in the two groups but there was a tendency to more frequent episodes of haemodynamic deterioration in the knee–chest position. (*Br. J. Anaesth.* 1997; **79**: 609–611).

Key words

Anaesthetic techniques, subarachnoid. Surgery, spinal. Position, effects. Anaesthetics local, bupivacaine.

Although general anaesthesia is used more often than spinal anaesthesia, the latter is gaining popularity in microscope-assisted surgery of herniated lumbar discs.[1 2] Intrathecal puncture can be performed before positioning for surgery or with the patient in the prone knee–chest position.

The spread of spinal anaesthesia with the slightly hypobaric bupivacaine solution and associated haemodynamic changes may be different in the knee–chest position compared with the supine horizontal position. In addition, decreased venous flow in the lower extremities of patients in the knee–chest position[3] may predispose to lowering of cardiac output[4] and arterial pressure.

In this randomized study, we have compared spinal anaesthesia with plain bupivacaine performed in patients in the knee–chest and horizontal side positions during induction of block.

Patients and methods

The study was approved by the Ethics Committee of the hospital. After obtaining informed consent, we studied 40 patients, ASA I–II, aged 24–61 yr, undergoing primary lumbar disc surgery under spinal anaesthesia (table 1). All patients received diazepam 0.15–0.2 mg kg^{-1} orally as premedication, 45–60 min before anaesthesia. Clinical monitoring included ECG, non-invasive arterial pressure (oscillotonometer) and haemoglobin oxygen saturation ($S\mathrm{p}_{\mathrm{O}_2}$). Ringer's acetate 100–200 ml was given i.v. before local anaesthetic injection and then approximately 8 ml kg^{-1} in 20 min. Thereafter the infusion rate was reduced to 100–200 ml h^{-1}.

Patients were allocated randomized to one of two groups. In the prone knee–chest group, patients received the subarachnoid injection after first positioning themselves in the knee–chest position on the operation table. Because of this position and the small size of the spinal needle there was usually no free flow of cerebrospinal fluid (CSF) and hence the correct position of the needle tip was ascertained by aspirating CSF (0.2–0.3 ml) through the needle before injecting the anaesthetic. The table was then

E. LAAKSO*, MD, M. PITKANEN, MD, PHD, J. KYTTÄ, MD, PHD, P. H. ROSENBERG, MD, PHD, Department of Anaesthesiology, Helsinki University Central Hospital, Toolo Hospital, FIN-00260 Helsinki, Finland. Accepted for publication. July 7, 1997

*Address for correspondence: Toolo Hospital, Topeliuksenkatu 5, 00260 Helsinki, Finland.

turned so that the "hip–shoulder joint" line was 20° head-up with respect to the horizontal line.

Patients in the supine side horizontal group received the subarachnoid local anaesthetic injection in the horizontal side position and were turned immediately into the supine position for 20 min. These patients were then placed in the knee–chest position with the assistance of personnel.

In both groups subarachnoid block was performed with a 27-gauge Quincke-type needle in the L2–3 interspace and 3.0 ml of 0.5% bupivacaine were injected. The level of spinal analgesia was tested by pinprick at 5, 10, 15, 20, 30, 45 and 60 min, and thereafter at 30-min intervals after the subarachnoid injection.

If systolic arterial pressure decreased by more than 25% from the preoperative value and the patient had clinical symptoms of arterial hypotension, or systolic arterial pressure decreased to less than 90 mm Hg, ephedrine 5 mg was given i.v. If heart rate decreased to >25% or less than 45 beat min^{-1}, atropine 0.5 mg was given i.v.

All comments by patients were recorded and patients were interviewed by one of the investigators on the next day. Patients left hospital on the second day after operation, or later, and they were asked to report any further symptoms possibly associated with anaesthesia.

For data analysis, descriptive statistics were used. For comparisons between groups, ANOVA and the Mann–Whitney *U* test were used, where appropriate. $P<0.05$ was considered statistically significant.

Results

Patients characteristics were comparable in the two groups (table 1). In three cases in the prone knee–chest group the 27-gauge needle was changed for a 25-gauge needle because of difficulties with identification of the subarachnoid space and multiple puncture attempts. There was no significant difference in the maximum median level of analgesia between the groups (fig. 1). The time to maximum spread (median dermatomal level) of analgesia was 45 min in both groups. The highest individual level of analgesia was T3 in the prone knee–chest group and T1 in the supine side horizontal group.

Recovery from spinal anaesthesia was similar in both groups, the median dermatomal level of pinprick analgesia was L2, 210 min after spinal block in both groups.

The mean maximum decrease in systolic arterial pressure from baseline was 30 mm Hg (SD 19, individual maximum decrease 66 mm Hg) in the prone knee–chest group compared with 13 mm Hg (SD 17, individual maximum decrease 79 mm Hg) in the supine side horizontal group. This difference, calculated using the Mann–Whitney *U* test, was significant ($P=0.0398$).

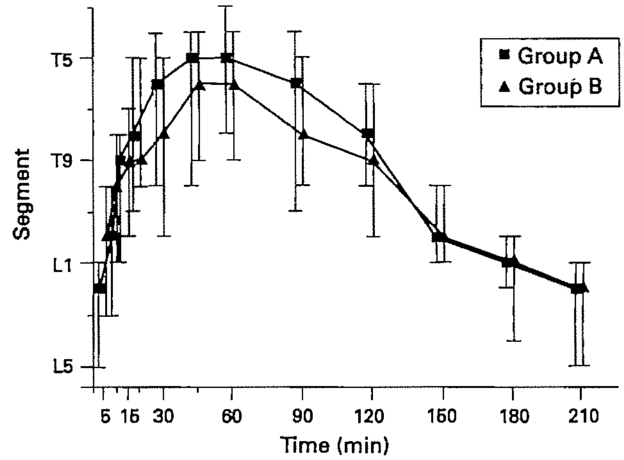

Figure 1 Spread of pinprick analgesia (median and quartiles) after subarachnoid injection of 3.0 ml of plain 0.5% bupivacaine at the L2–3 interspace. Group A=knee–chest position and group B=supine side horizontal position.

In the prone knee–chest group, ephedrine was needed in six patients compared with three in the supine side horizontal group. It should also be noted that vasopressors in the prone knee–chest group were not given earlier than 15 min from injection of the spinal anaesthetic. In the supine side horizontal group, all three patients needing vasopressor received it within the first 10 min from spinal injection.

Six patients in the prone knee–chest group needed atropine or glycopyrronium (four of these also received ephedrine) and two in the supine side horizontal group (one patient also received ephedrine) received atropine for bradycardia.

Because of mild incisional pain, the skin was infiltrated with local anaesthetic in one patient in the supine side horizontal group. One patient in the prone knee–chest group had insufficient cephalad spread of analgesia and was given an extra intrathecal dose of 1.0 ml of 0.5% bupivacaine 40 min after the initial spinal anaesthetic injection, before the start of operation. Another patient in the prone knee–chest group received 1.5 ml of 0.5% bupivacaine extradurally during surgery, 60 min after the intrathecal injection and was pain free within 2–3 min.

One patient in the prone knee–chest group had a sudden decrease in the level of analgesia from T12 to L3 after leakage of cerebrospinal fluid (CSF) through an unintentional tear in the dura. Soon after the patient complained of mild pain and was given two doses of fentanyl 50 μg.

Duration of surgery varied between 20 and 112 min (mean 56 min). The main complaint of patients

Table 1 Patient characteristics (mean (SD or range) or number)

	Sex (F/M)	Age (yr)	Height (m)	Weight (kg)	Duration of operation (min)
Prone knee–chest group	7/13	41 (24–57)	1.74 (0.08)	78 (17)	62 (25)
Supine side horizontal group	6/14	40 (24–61)	1.77 (0.09)	78 (4)	51 (19)

during surgery was numbness and ache in the arms and shoulders because of the position on the operating table. Seven patients (four in the prone knee–chest group, three in the supine side horizontal group) received light sedation, either diazepam 2.5–5.0 mg or midazolam 1.0–4.0 mg i.v. Two patients (both in the prone knee–chest group) also received a short infusion of propofol at a rate of 2 mg kg^{-1} h^{-1} or less near the end of operation.

All patients had complete sensory and motor recovery from spinal anaesthesia and none reported symptoms of radiating aching or pain in the buttocks or legs, or post-dural puncture headache (PDPH). None of the study patients reported backache or PDPH at a later stage. All patients were satisfied with this type of anaesthesia.

Discussion

We have found that there was no difference in the rate and spread of anaesthesia whether the subarachnoid local anaesthetic injection was performed with the patient in the horizontal side position or in the knee–chest position. However, when the patient was in the knee–chest position during induction of anaesthesia there was a tendency to greater hypotension and bradycardia compared with the horizontal position. It can be postulated that when the horizontal position is used for the first 20 min, patients have more time to accommodate to vasodilatation of the lower limbs. As was demonstrated in our earlier ultrasonographic study with healthy unanaesthetized volunteers,[3] there seems to be a tendency to venous blood pooling in the lower limbs in the knee–chest position. When this is combined with vasodilatation caused by anaesthesia the effect on venous return to the heart can be severely impaired.[5,6] In fact, even without anaesthesia, Wadsworth, Anderton and Vohra[4] were able to demonstrate a 20% reduction in cardiac index of volunteers placed in the knee–chest position.

The quality of anaesthesia was good for surgical purposes in all but one patient who needed an additional intrathecal dose of bupivacaine. Another patient received bupivacaine 7.5 mg into the exposed extradural space at the site of surgery 60 min after the original spinal anaesthesia. It is interesting that such a small extradural dose sufficed to abolish painful sensations within a few minutes, suggesting that this was a direct local effect on a painful spot rather than a spinal effect. The sedation needed in seven patients was based mostly on inconvenience felt in the hands and shoulders. Mild sedation with benzodiazepines or propofol appears to be beneficial in such cases. However, it is important that the depth of sedation is kept so light that the patient remains co-operative and maintains good spontaneous breathing.

The case of dural leakage during surgery was interesting. It was assumed that the dural lesion allowed leakage of CSF and local anaesthetic and this resulted in an immediate reduction in cephalic extension of sensory analgesia. After closure of the lesion the local anaesthetic seemed to have been redistributed within the cerebrospinal fluid and the previous level of analgesia was re-instated. The loss of some bupivacaine by leakage may have reduced the duration of block.

Spinal anaesthesia performed before the patient has assumed the surgical position has been a routine for low back operations, including laminectomy, lumbar disc operations and spinal fusions.[2,7,8] In a survey of 28 395 patients undergoing lumbar laminectomy for discogenic radiculopathy, Ramirez and Thisted reported that 7% of operations (1988 operations) were performed under spinal anaesthesia. No complications could be related exclusively to this technique.[9] In another retrospective review, Tezlaff and colleagues[2] reported 23 patients whose operations were performed during spinal anaesthesia, including laminectomies, lumbar disc operations and fusions. There were no failures of spinal anaesthesia, anaesthetic complications or PDPH.

Pharmacokinetics of vecuronium during acute isovolaemic haemodilution

F. S. XUE, X. LIAO, S. Y. TONG, J. H. LIU, L. LI, Q. ZOU AND L. K. LUO

Summary

To evaluate the effect of acute isovolaemic haemodilution on the pharmacokinetics of vecuronium, we studied 13 patients undergoing haemodilution during surgery and 13 control patients. General anaesthesia was induced with thiopentone 4–6 mg kg^{-1} and fentanyl 2–4 μg kg^{-1}, and maintained with enflurane and 60% nitrous oxide in oxygen. The haemodilution patients underwent major elective plastic surgery with an anticipated surgical loss of more than 600 ml. Haemodilution was achieved by drainage of venous blood and i.v. infusion of lactated Ringer's solution and 6% dextran, during which the packed cell volume and haemoglobin concentration decreased from 45% to 28.1% and from 14.7 g dl^{-1} to 9.1 g dl^{-1}, respectively. After administration of a bolus of vecuronium 100 μg kg^{-1}, an improved fluorimetric assay was used to measure the plasma concentrations of vecuronium for 5 h. The results showed that the disposition kinetics of vecuronium were best described mathematically by a three-compartment open model in the two groups. The mean volume of the central compartment and volume of distribution at steady state were 42.3 (SD 11.8) ml kg^{-1} and 168.4 (31.5) ml kg^{-1}, respectively, in control patients, and significantly greater (55.2 (13.4) ml kg^{-1} and 225.9 (53.3) ml kg^{-1}) in the haemodilution patients ($P<0.05$). The elimination half-life was 50.3 (11.5) min in control patients and significantly greater (68.2 (15.1) min) in the haemodilution patients ($P<0.05$). The half-lives of fast distribution and distribution, mean residual time, area under the plasma concentration curve and plasma clearance were unchanged in patients who underwent haemodilution compared with the control group. (*Br. J. Anaesth.* 1997; **79**: 612–616).

Key words
Neuromuscular block, vecuronium. Pharmacokinetics, vecuronium. Blood, haemodilution.

Vecuronium is a non-depolarizing neuromuscular blocking agent with an intermediate clinical duration of action. In recent years, the possible factors influencing the pharmacokinetics of vecuronium, such as age,[1 2] hepatic[3] and renal[4 5] insufficiency, pregnancy[6] and hypothermia,[7] have been studied extensively. Preoperative isovolaemic haemodilution, which is an effective method of reducing homologous blood transfusion during surgery, is often associated with haemodynamic changes, changes in regional organ blood flow, blood chemistry, blood volume and body fluid distribution.[8–13] Previous studies have shown that the potencies of suxamethonium, pancuronium and tubocurarine are increased and the duration of action prolonged, after preoperative normovolaemic haemodilution.[14 15] However, there are no studies on the pharmacokinetics of vecuronium during acute isovolaemic haemodilution in adult patients. In this study, we have measured plasma concentrations of vecuronium using an improved fluorimetric technique and observed the effect of acute isovolaemic haemodilution on the pharmacokinetics of vecuronium.

Patients and methods

After obtaining informed consent and approval from the hospital's Ethics Committee, we studied 13 patients undergoing acute isovolaemic haemodilution during surgery and 13 patients not receiving haemodilution. All patients were ASA I, aged 18–39 yr and were undergoing elective plastic surgery. The haemodilution patients underwent major plastic surgery with an anticipated surgical loss of more than 600 ml. Three patients underwent breast reconstruction with a free flap, five patients received extensive head and face plastic surgery, four patients had an abdominoplasty and one patient a maxillectomy. Patients with cardiac and respiratory diseases were excluded. None suffered any disease or were receiving any drug known to alter neuromuscular function. Those with anaemia (haemoglobin concentration <12 g dl^{-1}) were also excluded.

Patients were premedicated with diazepam 0.2 mg

Correspondence to F. S. X.

kg^{-1} and atropine 0.01 mg kg^{-1} i.m., 1 h before anaesthesia. On arrival in the operating room, an i.v. catheter was inserted and general anaesthesia was induced with thiopentone 4–6 mg kg^{-1} and fentanyl 2–4 μg kg^{-1}. After topical anaesthesia with 2% lignocaine, the trachea was intubated without the aid of a neuromuscular blocking agent, and general anaesthesia was maintained with enflurane (1.5–2% expired concentration) and 60% nitrous oxide in oxygen. Fentanyl 2 μg kg^{-1} i.v. was supplemented as required. The lungs were ventilated (V_T=8–10 ml kg^{-1}, f=8–10 bpm) during surgery and $P_{E'CO_2}$ was maintained within normal limits.

After stable anaesthesia had been achieved in the haemodilution patients, 12–15 ml kg^{-1} of blood (approximately 20% of blood volume) were obtained from a cubital vein over a period of 15–20 min before the start of surgery and stored in a reservoir bag containing ACD solution. Simultaneously, a volume of Ringer's lactate solution, double or triple that of the withdrawn blood, and an equal volume of 6% medium molecular dextran (molecular weight 70 000 Da) were infused rapidly via a separate venous cannula. The packed cell volume (PCV) target after haemodilution was 25–30%. During surgery, blood loss was measured by swab and drape weighing and from suction bottles, and was replaced with Ringer's lactate solution and medium molecular dextran. Blood was reinfused only after major surgical loss was complete in the reverse order of collection through non-filtered infusion sets. Control patients only received Ringer's lactate solution 10–12 ml kg^{-1} h^{-1} during surgery. Haemodynamic variables remained stable throughout the study in all patients.

During surgery ECG, arterial pressure, heart rate, temperature and Sp_{O_2} were monitored continuously (Cardiocap, Datex Instrumentarium, Helsinki, Finland). Inspired and end-tidal concentrations of oxygen, carbon dioxide and nitrous oxide were measured and displayed digitally by an anaesthetic gas monitor (anaesthesia gas monitor type 1304, Bruel and Kjaer, Denmark). A cannula was placed in the radial or femoral artery for sampling. Arterial pH, Pa_{O_2}, Pa_{CO_2}, PCV and haemoglobin concentration were measured with a blood-gas electrolyte analyser (Model-5, Nova Biomedical Company, Hoboken, USA) before and during anaesthesia. Total plasma protein (TPP) and albumin (Alb) concentration were also measured using an automatic biochemical analyser (Type-550, Corning Medical Company, Oberlin, Ohio, USA). Body core temperature was maintained at 36–37 °C.

PLASMA SAMPLING

When anaesthesia was stable or haemodilution was complete, an i.v. bolus of vecuronium 100 μg kg^{-1} was administered. Blood samples (4 ml) were collected from an antecubital vein before and at 1, 3, 5, 10, 15, 20, 30, 45, 60, 90, 120, 180, 240 and 300 min after administration of vecuronium. Each blood sample was centrifuged within 5 min, and 1 ml of plasma was acidified immediately by adding 150 μl of NaH_2PO_4 1 mol $litre^{-1}$ to prevent hydrolysis of vecuronium. Spontaneous hydrolysis of vecuronium in plasma occurs at body pH and room temperature at a rate of 0.35% when determined in our laboratory. The samples were then frozen at −20 °C until subsequent analysis. Plasma concentrations of vecuronium were measured by a modified fluorimetric assay described originally for pancuronium by Kersten, Meijer and Agoston.[16] The fluorescent intensity of the sample was measured by a spectrofluorophotometer (model RF450; Shimadzu Corporation, Japan). The lower limit of sensitivity of this technique was 5 ng ml^{-1} for vecuronium. The coefficients of variation at concentrations of 10 (n=8), 250 (n=10) and 1000 ng ml^{-1} (n=10) were 9.7%, 4% and 0.5%, respectively, in our laboratory. None of the drugs used during anaesthesia interfered with assay of vecuronium.

PHARMACOKINETICS ANALYSIS

Individual data points from the time–plasma concentration curve of vecuronium were stored on a computer and analysed with a $3P_{87}$ program edited by the Chinese Association of Mathematical Pharmacology (Beijing, People's Republic of China). Plasma vecuronium concentration–time data were fitted to both two- and three-compartment mammillary pharmacokinetic models using non-linear, least-squares regression. Models were compared statistically using the F test to determine the simplest model which accounted for the data of each patient. In all patients, a three-compartment pharmacokinetic model was preferred statistically to a two-compartment model, using the technique of Boxenbaum, Riegelmann and Elashoff.[17] Therefore, the following variables were calculated using standard formulae from the $3P_{87}$ program: half-lives of rapid distribution ($T_{1/2}{}^{\pi}$), distribution ($T_{1/2}{}^{\alpha}$) and elimination ($T_{1/2}{}^{\beta}$), volume of the central compartment (V_c), volume of distribution at steady state (V^{ss}), area under the plasma concentration curve (AUC), mean residual time (MRT) and plasma clearance (Cl).

A POMS statistical software version 2.00 (Shanghai Scientific and Technical Publishers, Shanghai, People's Republic of China) was used for statistical analysis of the data. A chi-square test was used to compare sex distribution between the two groups. Other statistical analyses were made with the two-tailed non-parametric Mann–Whitney U test. $P<0.05$ was considered significant.

Results

There was no statistically significant difference between the two groups in age, body weight, height, preoperative temperature or duration of operation. Compared with preoperative values, concentrations of haemoglobin, PCV, total plasma protein and albumin during surgery decreased significantly in patients who had haemodilution but remained stable in the control group (table 1). Changes in arterial pH, Pa_{O_2} and Pa_{CO_2} in all the patients remained within normal limits throughout the study.

Compared with controls, plasma concentrations

of vecuronium in the haemodilution patients were lower during the initial 120 min after administration of the drug, but were higher from 120 to 300 min (fig. 1). Mean plasma concentrations of vecuronium were significantly different between the two groups at each time, except at 120, 180 and 240 min.

The concentration–time data for all patients were well described by a three-compartment open model. The pharmacokinetics of vecuronium for the two groups are summarized in table 2. In the haemodilution patients, V_c and V^{ss} were greater ($P<0.05$) and the elimination half-live ($T_{1/2}^{\beta}$) was longer ($P<0.05$) compared with controls. The half-lives of rapid distribution ($T_{1/2}^{\pi}$) and distribution ($T_{1/2}^{\alpha}$), AUC, MRT and *Cl* were not significantly different between the two groups.

Discussion

In this study, a classical fluorimetric assay was used to determine the plasma concentration of vecuronium: the lower limit of sensitivity of the method is 5 ng ml^{-1}, which is sufficient to detect vecuronium in plasma for up to 5 h after a bolus of 100 μg kg^{-1}. This fluorimetric assay had been used extensively to study the pharmacokinetics of vecuronium in children and adults,[1 4 18 19] but as it measures both vecuronium and its deacetylated metabolites, its lack of specificity could be criticized. In previous studies[1 4] thin layer chromatography was conducted after the assay to separate and estimate the proportion of metabolites. Even in adults with chronic renal failure,[4] none of the metabolites could be detected in plasma at any time. However, comparison between the fluorimetric and the more specific high-pressure liquid chromatography method (HPLC)[20] suggests that metabolites may account for 15% of the total plasma concentration of vecuronium over a range of 200–1000 ng ml^{-1}. But even if the presence of low concentrations of vecuronium metabolites slightly altered the pharmacokinetic data, there is no reason to suggest that such metabolites may be present in a greater proportion in haemodilution patients than in controls. Thus we believe that comparison of the pharmacokinetic data between the two groups is valid. Previous studies have suggested that the pharmacokinetics of vecuronium measured by fluorimetric assay were similar to those determined by HPLC or gas chromatography.[1 16] Furthermore, the pharmacokinetic data of vecuronium obtained in controls were within the range of those reported in previous studies.[5 6 18 19 21]

The most important difference between the control patients and those undergoing haemodilution was the greater volume of distribution of vecuronium in patients receiving haemodilution. Our data showed that in comparison with controls, the volume of the central compartment and volume of distribution of vecuronium at steady state in patients undergoing haemodilution increased by 33.4% and 25.5%, respectively. After administration of vecuronium 100 μg kg^{-1}, mean plasma concentrations of vecuronium in controls were 1.78 μg ml^{-1} at 1 min and 1.05 μg ml^{-1} at 3 min respectively, which were significantly higher than those in the haemodilution patients (1.14 μg ml^{-1} and 0.89 μg ml^{-1}; $P<0.05$). Vecuronium is a water soluble non-depolarizing neuromuscular blocking agent. It distributes mainly in extracellular fluid after i.v. administration.[22] Possible explanations for our results include rapid infusion of large volumes of crystalloid and colloidal solutions markedly increasing blood volume.[8] Haemodilution also decreases blood viscosity, increases cardiac output and velocity of blood flow. Thus blood flow to vessel organs such as the liver, lungs, kidneys, heart and brain is increased, possibly increasing metabolism and excretion of drugs.[9–11] In addition, haemodilution decreases plasma colloid oncotic pressure because of a decrease in plasma protein concentration. A large quantity of infused crystalloid solution could therefore enlarge the extracellular fluid volume.[12]

Vecuronium is eliminated mainly by the liver, and to a lesser extent unchanged by the kidney.[4 18] In this study, plasma clearance of vecuronium in patients undergoing haemodilution increased by 16.2%. This may be a result of the increase in hepatic and renal blood flow during haemodilution.[10 13] In addition, decreased plasma protein concentration during haemodilution might increase the ratio of unbound to bound vecuronium in plasma. As only free drug is filtered at the glomerulus, renal elimination may be increased. However, the difference in plasma clearance between the two groups was not statistically significant, which might be related to the small sample size and large individual differences. Although the elimination half-life of a drug is inversely proportional to plasma clearance (which was increased in the haemodilution patients), the elimination half-life of vecuronium was markedly prolonged in the haemodilution patients. This may be related to their larger volume of distribution at steady state.

In this study, the decay in plasma concentrations of vecuronium occurred in a triexponential manner, in contrast with that described in earlier studies[5 21 23] where plasma concentrations declined biexponentially. Possible factors that may explain this discrepancy are differences in the methods used to measure drug concentrations, different doses of vecuronium or duration of plasma sampling. In one study,[23] plasma concentrations of vecuronium measured by a relatively insensitive HPLC method (lower limit of detection 50 ng ml^{-1}) were observed for only 90 min after injection of vecuronium. Consequently, the larger part of the slower, terminal elimination phase was probably not detected. In another study, also using HPLC,[5] a larger dose of vecuronium (0.28 mg kg^{-1}, five times the recommended ED_{95} dose) was used in order to measure plasma concentrations for a longer period. A large dose of a drug can, in principle, lead to non-linear pharmacokinetic processes, with a consequent shallow rate of decay in the early phases of plasma concentration decline, and the merging of the early and late distribution slopes. Perhaps for this reason Fahey and colleagues[5] selected a biexponential function to describe the plasma decay curve of vecuronium, even though they detected the plasma decay curve of vecuronium for 4 h. In the study of Lebrault and colleagues[21] using a fluorimetric assay with a lower limit of sensitivity of 25 ng ml^{-1}, not only was a larger dose of vecuronium administered (0.2 mg kg^{-1}, 3.6 times the recommended ED_{95} dose), but plasma concentrations were observed for a shorter period (210 min) compared with our study.

However, in studies using very sensitive mass spectral analysis (level of detection 2 ng ml^{-1})[23] or a modified fluorimetric assay (level of detection 5 ng ml^{-1})[19] to measure plasma concentrations after administration of vecuronium 25–50 μg kg^{-1} or 100 μg kg^{-1} for 5–8 h, the authors found that the disposition kinetics of vecuronium were best described by a model with three compartments and with pharmacokinetic variables that agreed closely with those generated in this study. Mass spectrometry is the most sensitive assay method available to date and it specifically measures only unchanged vecuronium (or any of its metabolites, if so desired). Therefore, the results of this study support the views of Bencini and co-workers[4] that vecuronium disposition kinetics are best described by a three-compartment open model.

Early studies showed that the duration of neuromuscular effect after moderate doses of vecuronium (100 μg kg^{-1}) is governed by the distribution phase rather than the elimination phase. However, after a large dose (200–300 μg kg^{-1}) or repeated doses, recovery from paralysis probably occurs during the elimination phase.[22] On the basis of our results, it was assumed that compared with controls, the larger distribution volume of vecuronium in the haemodilution patients would result in lower plasma concentrations and thus increased dose requirements to achieve comparable neuromuscular block. In addition, the clinical duration of a lower dose of vecuronium may be shorter in patients undergoing haemodilution than in controls because of the larger distribution volume at steady state and higher plasma clearance. But after large or repeated doses, the clinical duration of vecuronium in the haemodilution patients may be prolonged because of the longer elimination half-life.

However, it must be remembered that haemodilution may also be associated with significant changes in plasma protein concentrations. The pharmacological effect of a drug is highly dependent on its degree of plasma protein binding, as only unbound drug diffuses through membranes and is thus available for binding to receptors and exerting its pharmacological action. Schuh reported[14] that the potency of pancuronium was increased during haemodilution, which may be related to a decrease in plasma protein binding. As the protein-bound fraction of vecuronium (30%) is similar to that of pancuronium (29%),[24] any increase in the plasma concentration of unbound vecuronium during haemodilution may outweigh the influences of a larger volume of distribution and a higher plasma clearance on its neuromuscular blocking effects.

LABORATORY INVESTIGATIONS

Effects of volatile anaesthetics on spontaneous action potential firing of cerebellar Purkinje cells *in vitro* do not follow the Meyer–Overton rule

B. ANTKOWIAK, H. HENTSCHKE AND K. KIRSCHFELD

Summary

We have investigated in rat brain slices the effects of the volatile anaesthetics enflurane, isoflurane and halothane on spontaneous discharge patterns and mean firing rates of cerebellar Purkinje cells. In the absence of these anaesthetics, Purkinje cells fired bursts of action potentials separated by quiescent periods lasting less than 2 s. Mean discharge rates were 10.8 (SEM 0.4) Hz at 23±1 °C and 25.6 (1.2) Hz at 35±1 °C. The agents exhibited qualitatively different effects when applied at concentrations corresponding to 1–3 MAC. Enflurane markedly lengthened burst and inter-burst durations. Isoflurane acted in a similar manner, but effects were less pronounced. In contrast with isoflurane and enflurane, halothane shortened burst durations. At concentrations corresponding to 1–1.5 MAC, halothane, isoflurane and enflurane significantly depressed action potential firing by 15–30% ($P<0.05$). Enflurane 1.2 mmol litre^{-1} (2.0 MAC), isoflurane 0.9 mmol litre^{-1} (2.8 MAC) and halothane 0.9 mmol litre^{-1} (3.8 MAC) depressed spontaneous spike rates by 50%. The changes in discharge patterns and the concentration-dependent decrease in the firing rates were similar at 23±1 °C and 35±1 °C. In summary, we observed that neither the anaesthetic-induced alterations in spontaneous discharge patterns nor the EC_{50} values of the concentration-dependent depression of the mean firing rates were in accordance with the Meyer–Overton rule. However, at clinically relevant concentrations, depression of average spike rates did not differ significantly between the anaesthetics and thus followed the rule. Our results suggest that anaesthetic actions, which are in accordance with the rule, are frequently masked by several side effects. (*Br. J. Anaesth.* 1997; **79**: 617–624).

Key words
Anaesthetics volatile, halothane. Anaesthetics volatile, isoflurane. Anaesthetics volatile, enflurane. Brain, cerebellum. Brain, Purkinje neurones. Theories of anaesthetic action, Meyer–Overton.

The efficacy of volatile general anaesthetics in depressing painful stimuli-evoked movements in mammals is predicted well by the Meyer–Overton rule which correlates the potency of these compounds with fat solubility.[1 2] For a molecular mechanism, possibly involved in the anaesthetic state, it is regarded as a prerequisite that the effects follow this rule.[3]

Anaesthetic-induced inhibition of motor responses, such as the righting reflex, seems to be related mainly to the depressant effects observed in the spinal cord.[4 5] Volatile anaesthetics also reduce neuronal activity in many other parts of the central nervous system, including the hippocampus,[6–11] neocortex,[12] thalamus[13 14] and olfactory cortex.[15 16] In several studies, the decrease in neuronal activity observed during anaesthesia was attributed to various mechanisms, for example activation of potassium channels,[17 18] depression of spike after hyperpolarizations,[12] inhibition of sodium channels,[19] depression of synaptic excitation[20] and potentiation of synaptic inhibition.[21] However, the question remains as to which of these examples follows the Meyer–Overton rule.

In the nervous system, information is coded into spike patterns and spike rates. We assume that anaesthetic-induced alterations in firing patterns of central neurones should be also in accordance with the rule, given that the underlying molecular mechanisms are related to the state of general anaesthesia. At present, little information is available on how volatile anaesthetics affect spike patterns in different parts of the central nervous system.

We have investigated the effects of halothane, isoflurane and enflurane on spontaneous action potential firing of cerebellar Purkinje neurones *in vitro*. Purkinje cells exhibit spontaneous activity even in acutely isolated brain slices.[22–24] This enabled us to test the Meyer–Overton rule by comparing the effects of three anaesthetics on discharge patterns and mean firing rates.

Materials and methods

DETERMINATION OF MAC VALUES

Anaesthesia was induced in 13–16-day-old Sprague Dawley rats of both sexes in Plexiglas boxes with a

gas flow of approximately 2 litre min^{-1}. The desired vapour concentrations of volatile anaesthetics were delivered by calibrated vaporizers (Draeger, Germany). EC_{50} values for general anaesthesia were determined as described previously.[25]

PREPARATION OF CEREBELLAR BRAIN SLICES

Slices were prepared according to procedures similar to those described by Edwards and colleagues.[26] In brief, 13–16-day-old rats were anaesthetized deeply with enflurane, isoflurane or halothane, decapitated and the brains removed rapidly. Brains were stored for 10–12 min in ice-cold artificial cerebrospinal fluid (ACSF) consisting of (mmol litre^{-1}): NaCl 125, KCl 2.5, NaH_2PO_4 1.25, $MgCl_2$ 1, $NaHCO_3$ 26, $CaCl_2$ 2 and glucose 25. The cerebellum was glued onto a Teflon block and 250–300-μm thick sagittal slices were cut with a vibratome (Campdgen, UK). Slices were stored in a bath of ACSF at room temperature bubbled with 95% oxygen and 5% carbon dioxide. They were then transferred to the recording chamber 1–6 h later and perfused continuously with ACSF at a flow rate of approximately 1 ml min^{-1}.

STAINING OF PURKINJE CELLS

Neurones in cerebellar slices were filled with Biocytin by means of the patch–clamp technique.[27] Standard immunocytochemical methods were used for further processing.[27 28]

EXTRACELLULAR RECORDINGS

Slices were viewed under low magnification with an inverted microscope. The typical layering of sagittal cerebellar slices was well visible. ACSF-filled glass electrodes with resistances of approximately 5 MΩ were positioned on the surface of the Purkinje cell layer (fig. 2). They were advanced into the slices until extracellular spikes exceeding 300 μV in amplitude were observed and a single unit could be discriminated clearly. Noise amplitude was 20–100 μV.

CONTROL OF EXPERIMENTAL TEMPERATURE

Experiments were carried out at either 22–24 °C or 34–36 °C. The recording chamber consisted of a metal frame with a glass bottom. A heating wire was glued onto the metal frame. In cases where experiments were carried out at body temperature, the frame was heated by passing an appropriate DC current through the heating wire.

PREPARATION AND APPLICATION OF TEST SOLUTIONS

Test solutions were prepared by dissolving the anaesthetics in the ACSF according to the method described by Wakamori, Ikemoto and Akaike.[29] For calculating MAC values, the concentrations proposed by Franks and Lieb were used.[30] Thus 1 MAC corresponded to aqueous concentrations of halothane 0.25 mmol litre^{-1}, isoflurane 0.32 mmol litre^{-1} and enflurane 0.62 mmol litre^{-1}. Anaesthetics were applied via bath perfusion using syringe pumps (ZAK, Germany) which were connected via Teflon tubing to the experimental chamber. Flow rate was approximately 1 ml min^{-1}. When switching from ACSF to drug-containing solutions, the medium in the experimental chamber was replaced within 2 min by at least 95%. Effects on spike patterns were stable at approximately 5 min later. This delay may be attributed to diffusion of the test solution into the tissue. The time required to observe recovery increased with the concentration tested. With 0.5–2 MAC, full recovery was reached after 12–15 min and with 4–6 MAC after 30–60 min. For a single application, stable recording for at least 1 h was necessary.

DATA ANALYSIS

Data were low-pass filtered between 3 and 10 kHz, acquired on a PC with the digidata 1200 AD/DA interface and pClamp 6 software (Axon Instruments, USA) at 10–20 kHz. Simultaneously, records were stored on a Sony data recorder for further analysis. Extracellularly recorded spikes were counted on- or off-line using software event detectors. Spike rates were measured as mean spikes occurring in a period of 180–300 s. Inter-spike interval and burst analysis were performed by the pClamp program package. For statistical analysis the paired Student's *t* test was used. Unless otherwise stated, results are given as mean (SEM).

Results

SENSITIVITY OF ANIMALS TO VOLATILE ANAESTHETICS

In this study, brain slices were derived from 13–16-day-old Sprague–Dawley rats. We first assessed if these young animals and adult rats were equally sensitive to volatile anaesthetics. The

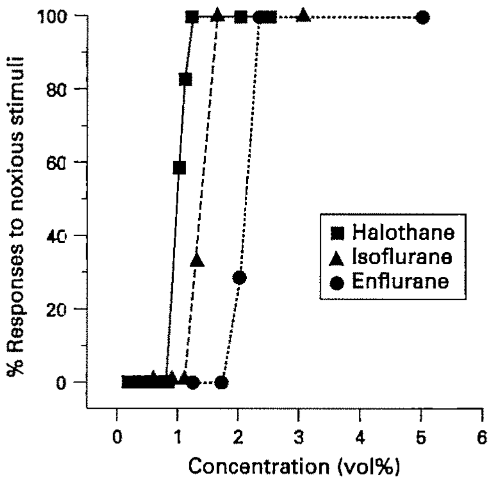

Figure 1 Effects of halothane, isoflurane and enflurane on painful stimuli-evoked movements of 2-week-old Sprague–Dawley rats which were used throughout the experiments. For each concentration, 15–20 animals were tested. EC_{50} values estimated from the dose–response curves are shown in table 1.

Table 1 Comparison of EC_{50}-values for general anaesthesia between about 2 week-old and adult Sprague Dawley rats. In the case of isoflurane the range given for adult rats indicates the variation in EC_{50}-values observed in the literature. References are given in brackets

	13–16-day old animals	Adult animals
Halothane	1.05 vol%	0.95 vol% [25]
Isoflurane	1.31 vol%	1.28–1.46 vol% [25, 31, 32]
Enflurane	2.10 vol%	1.95 vol% [25]

potencies of the anaesthetics were estimated from dose-dependent depression of painful stimuli-evoked movements according to a procedure reported previously.[25] The results summarized in figure 1 and table 1 show that, in the case of approximately 2-week-old rats, half-maximal depression by halothane, isoflurane and enflurane was observed at concentrations close to those reported for adult animals.[25 31–33]

EFFECTS OF VOLATILE ANAESTHETICS ON THE DISCHARGE RATES OF PURKINJE CELLS IN CEREBELLAR SLICES

Extracellular recordings were performed on 464 single Purkinje cells by positioning glass electrodes in sagittal cerebellar brain slices, as illustrated in figure 2A. Electrodes were advanced into the Purkinje cell layer until biphasic signals with amplitudes of approximately 0.2–1.0 mV could be discriminated clearly from baseline noise, which was usually less than 0.1 mV. In figure 2B a typical activity pattern, obtained at 23±1 °C, is shown. If inter-spike intervals lasting longer than 250 ms are considered as inter-burst intervals, the large unit fired bursts of action potentials separated by gaps of 0.2–2 s in duration. Bath application of tetrodotoxin 0.5 μmol $litre^{-1}$, which blocks Na^+ channels, reversibly suppressed these spontaneous voltage deflections (fig. 2B, $n=5$), indicating that they were generated by fast sodium spikes of a neurone close to the micropipette. To determine if the potency of the tested anaesthetics depended on a particular temperature, recordings were carried out at 23±1 °C or 35±1 °C. Increasing the temperature by approximately 10 °C shortened inter-burst durations and increased spontaneous firing rate by more than two-fold (fig. 2C, D).

In figure 3 representative examples of the effects of enflurane, isoflurane and halothane on firing pattern (fig. 3A) and discharge rate (fig. 3B) of a Purkinje cell

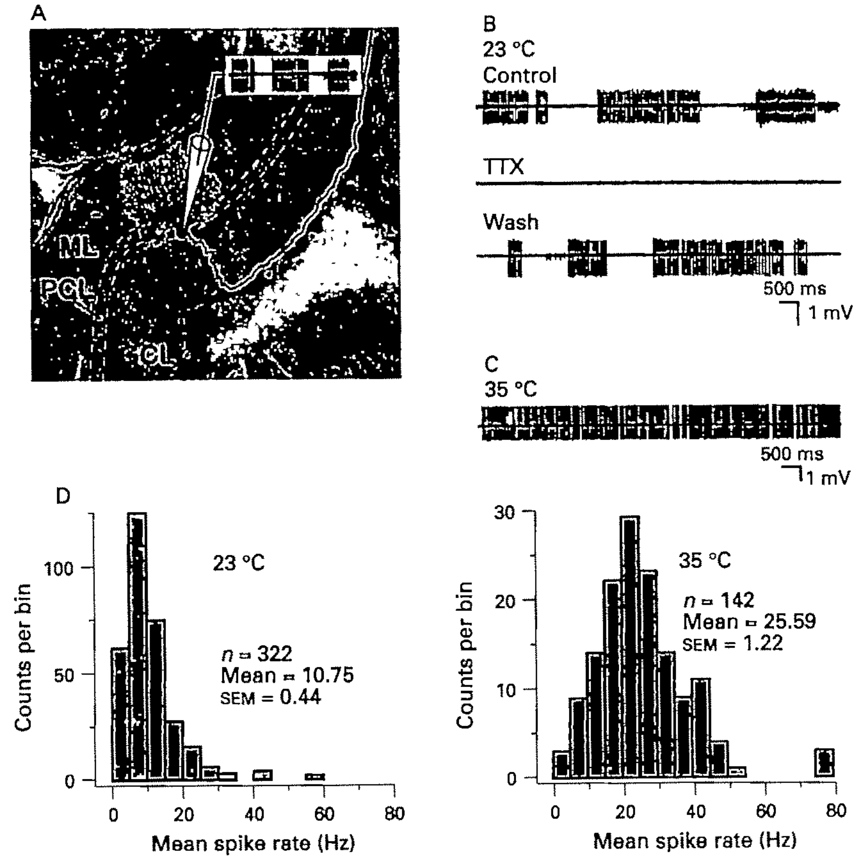

Figure 2 A· Photograph of a cerebellar brain slice, indicating the position of the Purkinje cells, layering and approach for obtaining extracellular recordings The Purkinje cell was labelled with Biocytin.[27 28] ML=Molecular layer; PCL=Purkinje cell layer; GCL=granule cell layer. Broken lines=approximate position of the Purkinje cell layer. Signals such as those indicated in the inset were obtained only when placing the recording electrode in the Purkinje cell layer where the somata of Purkinje cells lie densely packed. B: Extracellular recordings at 23±1 °C before, during and after treating the slice with tetrodotoxin (TTX). In the traces, two different cells can be discriminated easily by the different spike amplitudes. The neurones fired bursts of action potentials separated by gaps 0.2–5 s in duration. TTX 1 μmol $litre^{-1}$ reversibly depressed the occurrence of extracellularly recorded action potentials. C: Representative recording at 35±1 °C. Inter-burst durations shortened and mean spike rate increased. D: Distributions of mean spike rates obtained at 23±1 °C and 35±1 °C.

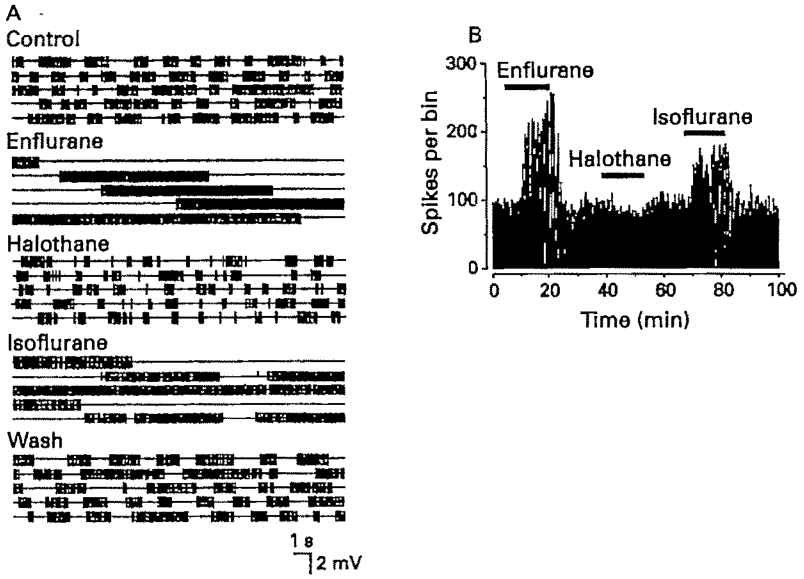

Figure 3 Effects of halothane 0.5 mmol litre^{-1}, isoflurane 0.64 mmol litre^{-1} and enflurane 1.24 mmol litre^{-1} on discharge patterns (A) and firing rates (B) of a cerebellar Purkinje cell. The concentrations corresponded to 2 MAC. The bin width in B was 10 s. The experiment was performed at 23±1 °C.

are shown. The anaesthetics were applied at concentrations twice as high as the EC_{50} value for general anaesthesia (2 MAC). They exhibited qualitatively different effects on the same neurone. Enflurane caused the cell to fire long bursts of action potentials, separated by gaps of approximately 10–20 s in duration. Spike patterns were similar in the presence of isoflurane, but burst and inter-burst durations were shorter (fig. 3B). In contrast with enflurane and isoflurane, halothane shortened burst durations and increased the firing rate within bursts. The effects were reversed on removing the anaesthetic.

The actions of volatile anaesthetics on the activity patterns of Purkinje cells were characterized further by comparing inter-spike interval histograms obtained from recordings carried out before, during and after treatment. The histograms shown in figure 4 were derived from three different cells. Under control conditions, all histograms exhibited a prominent peak at 50–100 ms and a smaller one at 1–2 s. These peaks corresponded to inter-spike intervals within the bursts and inter-burst durations

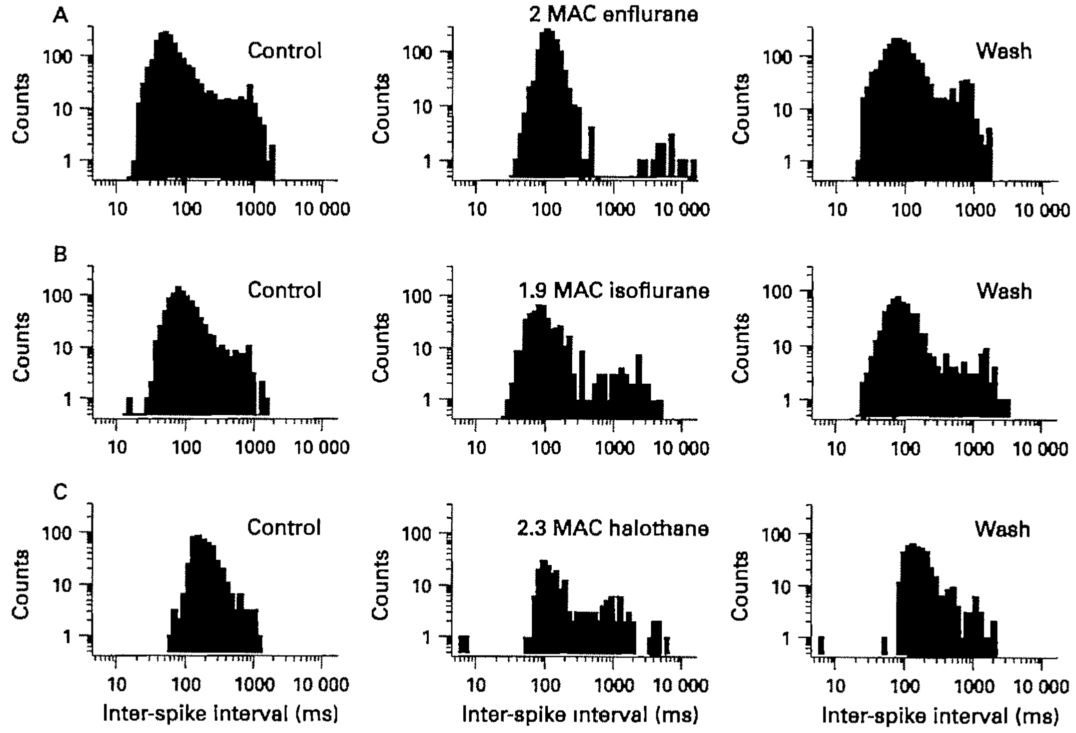

Figure 4 Inter-spike interval histograms derived from Purkinje cells in the absence and presence of volatile anaesthetics. The distributions were obtained from recordings which lasted 3 min. In these experiments the slices were exposed to enflurane 1.24 mmol litre^{-1} (A), isoflurane 0.61 mmol litre^{-1} (B) and halothane 0.57 mmol litre^{-1} (C). The corresponding MAC values are indicated.

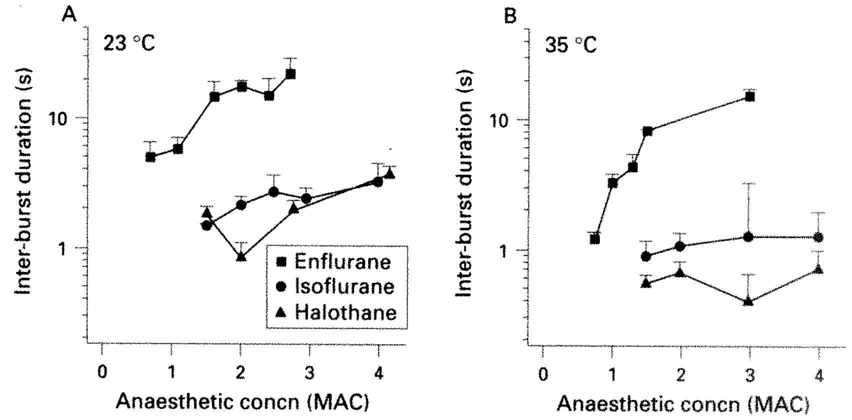

Figure 5 Effects of volatile anaesthetics on averaged inter-burst durations recorded at 23±1 °C and 35±1 °C. At both temperatures enflurane was most effective in increasing inter-burst durations. In the presence of 4 MAC of enflurane, spontaneous firing was suppressed completely (see fig. 6A).

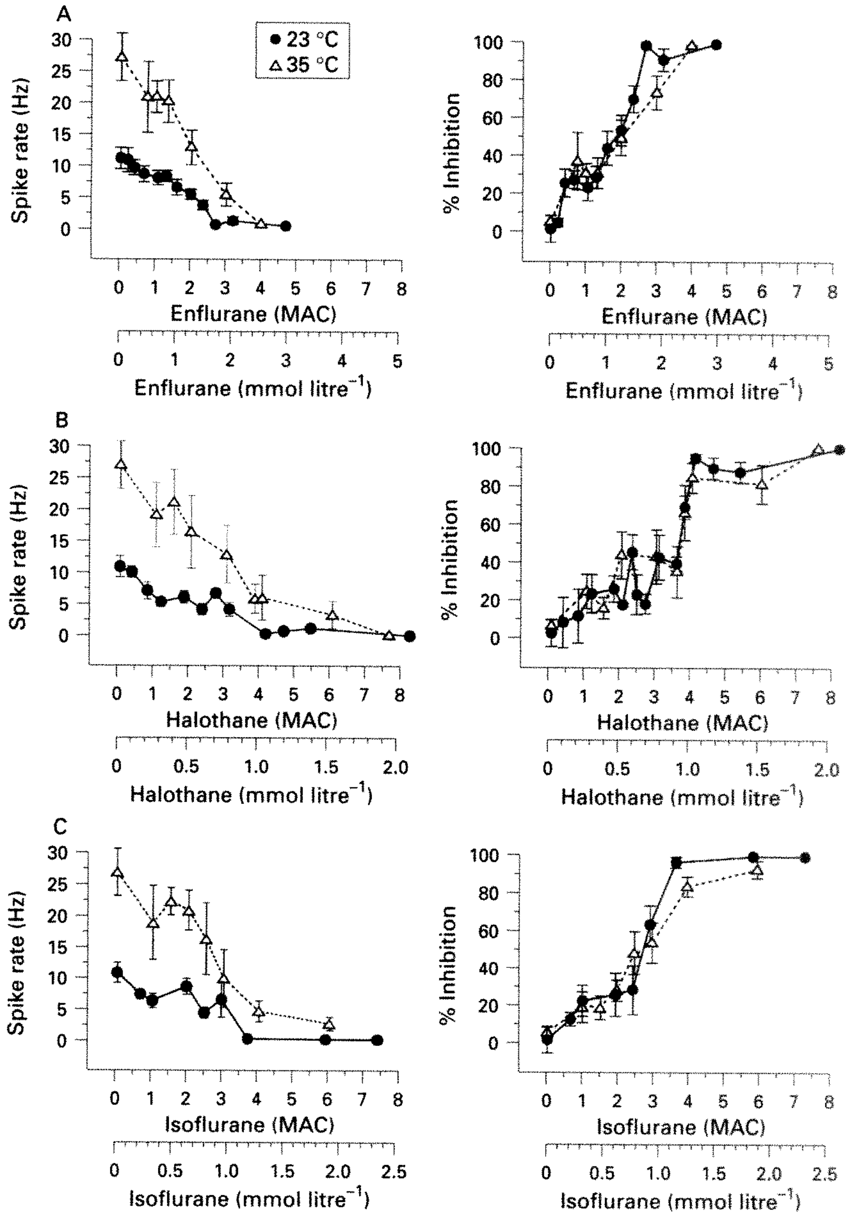

Figure 6 Concentration–response relationships for anaesthetic-induced depression of mean spike rates by enflurane (A), halothane (B) and isoflurane (C). Averaged spike rates monitored at 23±1 °C (●) and 35±1 °C (△) are shown in the left column. In the right column the effects of volatile anaesthetics were calculated by comparing action potential discharge rates before and during treatment.

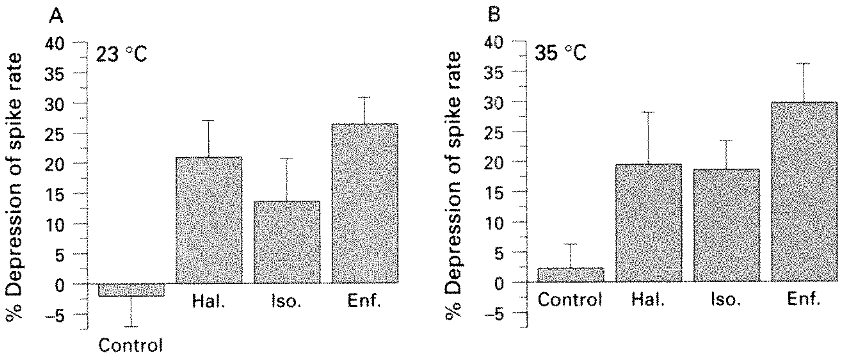

Figure 7 Depression of mean firing rates by clinically relevant concentrations of halothane (Hal.) isoflurane (Iso.) and enflurane (Enf.) at 23±1 °C and 35±1 °C. Data were pooled from those recordings in which concentrations corresponding to 1.0–1.5 MAC were applied. At both temperatures, the anaesthetics significantly depressed spontaneous spike rates ($P<0.05$).

Table 2 Half-maximal depression of spontaneous spike rates at 23±1 and 35±1°C. The corresponding MAC-values are given in brackets. Note that half-maximal depression occurred at similar anaesthetic concentrations, whereas the corresponding MAC-values differed considerably

	23±1 °C	35±1 °C
Halothane	0.9 mmol litre^{-1} (3.8 MAC)	0.9 mmol litre^{-1} (3.8 MAC)
Isoflurane	0.9 mmol litre^{-1} (2.8 MAC)	0.9 mmol litre^{-1} (2.8 MAC)
Enflurane	1.1 mmol litre^{-1} (1.8 MAC)	1.2 mmol litre^{-1} (2.0 MAC)

(for comparison see figs 2B and 3A). Inter-burst durations exceeding 3 s were not observed. The anaesthetics introduced long-lasting inter-burst intervals into the histograms; up to 12 s with enflurane and up to 7 s with isoflurane and halothane.

In figure 5, the concentration-dependent actions of volatile anaesthetics on the averaged inter-burst intervals are shown at different temperatures. The time criterion distinguishing between bursts and inter-bursts was set at 250 ms. The analysis was restricted to neurones exhibiting firing rates close to 10 Hz at 23±1 °C and to 25 Hz at 35±1 °C before exposing the cells to the anaesthetics. At both temperatures, enflurane increased inter-burst durations to approximately 10–20 s in a concentration-dependent manner. In the presence of halothane and isoflurane, inter-burst durations were 0.5–2 s. From the data shown in figures 3–5, it is evident that the effects of the anaesthetics were qualitatively different at both temperatures.

In spite of the discovery that anaesthetic-induced changes in the firing patterns of Purkinje cells did not follow the Meyer–Overton rule, it seemed possible that concentration-dependent depression of mean spike rates was in accordance with the predictions of the rule. In figure 6, the discharge rates and depression of spontaneous spiking are plotted against MAC values and concentrations of applied anaesthetics. Recordings were carried out at 23±1 °C and 35±1 °C. The effects at 0 MAC were obtained by applying ACSF and analysing the data according to the usual procedure. EC_{50} values interpolated from the concentration–response curves on depression of mean firing rates are summarized in table 2. The results displayed in figure 6 and table 2 show that although mean firing rates were affected considerably by changes in temperature, the relative decrease in spike rates caused by volatile anaesthetics were similar at both temperatures. Furthermore, EC_{50} values were not in accordance with the predictions of the Meyer–Overton rule (table 2).

The data presented in figure 6 demonstrate that, at least in the case of halothane and isoflurane, half-maximal inhibition of spike rates occurred at high concentrations, corresponding to approximately 3–4 MAC values. Although the decrease in spontaneous activity recorded at concentrations corresponding to 1.0–1.5 MAC was relatively low (15–30%), it was statistically significant for all anaesthetics (fig. 7). The data summarized in figure 7 show further that, at a range of clinically relevant concentrations depression of spike rates induced by enflurane, isoflurane and halothane did not differ significantly ($P<0.05$) and thus were in accordance with the predictions of the Meyer–Overton rule.

Discussion

COMPARSION WITH RELATED STUDIES

Nicoll and Madison analysed the effects of general anaesthetics on hippocampal and spinal neurones.[34] They observed that when cells were exposed to anaesthetics, membrane resting potential hyperpolarized and input resistance decreased. The results suggested that the efficacies of the agents were in accordance with the Meyer–Overton rule. Unfortunately, in this study concentrations 10 times higher than those required to produce anaesthesia were used.

The effects of halothane, isoflurane and enflurane in the hippocampus slice preparation were evaluated by Fujiwara and co-workers.[8] The authors found that at clinically relevant concentrations the order of anaesthetic potencies was not consistent with MAC values. As demonstrated in this study, anaesthetic-induced changes in firing patterns differed with respect to the agent used.

As reviewed recently, the actions of volatile anaesthetics in the spinal cord rather than those on higher brain structures seem to be responsible for depression of painful stimuli-evoked motor responses.[5] As the latter is predicted well by the Meyer–Overton rule, one might expect inhibition of the neuronal circuits in the spinal cord, mediating these movements, to also be in accordance with the rule. However, even here, several aspects of anaesthetic actions did not follow the rule.

In this study, we have provided evidence that halothane, isoflurane and enflurane, if applied at equal MAC values, alter the firing patterns of cerebellar Purkinje cells in different manners. Furthermore, the EC_{50} values, estimated from concentration-dependent depression of mean discharge rates, were not in accordance with the predictions of the rule. These two results cannot be explained by an unspecific mechanism, as suggested by the lipid theory.[3 35 36] Our findings in cerebellar slices argue against a unitary mechanism of anaesthetic action in this system and indicate specific effects. From the results on hippocampal, spinal and cerebellar neurones, it must be concluded that in the mammalian central nervous system effects of volatile anaesthetics which follow the Meyer–Overton rule are an exception rather than a common observation.

EFFECTS OF TEMPERATURE

Comparison of investigations elucidating the actions of volatile anaesthetics on central neurones is difficult since, because of methodological considerations, some studies were carried out at room temperature while others were conducted at body temperature.[37] It remains unclear to what extent the reported effects depended on the particular temperature chosen in the experiments. Our data indicate that the effects monitored at room temperature provide a reliable approximation for the effects at body temperature. Although increasing the temperature by approximately 10 °C more than doubled the spontaneous spike rate (fig. 2D), neither depression of mean firing rates (fig. 6) nor anaesthetic-induced alterations in discharge patterns (fig. 5) differed considerably between temperatures. A similar conclusion with regard to temperature dependence was obtained from a study on the actions of enflurane on GABA-mediated inhibitory postsynaptic currents (IPSC) monitored from voltage-clamped Purkinje neurones.[38] Although increasing the temperature from 23 to 35 °C reduced current decays of IPSC by 50%, the action of 1 and 2 MAC enflurane on IPSC kinetics proved to be temperature independent.

MOLECULAR MECHANISMS OF ANAESTHETIC ACTION IN CEREBELLAR SLICES

It is commonly assumed that the molecular mechanisms underlying general anaesthesia occur in a range of clinically relevant concentrations and are in accordance with the Meyer–Overton rule. In spite of considerable research efforts, these mechanisms are still a matter of controversy.[3 18 19 21] There is growing evidence that the $GABA_A$ receptor ion channel complex is a good candidate for such a mechanism.[3 21] We demonstrated recently that enflurane decreased action potential firing of Purkinje cells in acutely isolated cerebellar slices by increasing $GABA_A$-mediated synaptic inhibition.[38] At anaesthetic concentrations corresponding to 0.5–1.5 MAC, enflurane enhanced synaptic inhibition by approximately two-fold and thereby reduced the discharge rate by 20–30% (fig. 7 in Antkowiak and Heck[38]). As shown elsewhere, the actions of volatile anaesthetics on the $GABA_A$ receptor seem to follow the rule. This is consistent with the finding that at 1.0–1.5 MAC the decrease in firing rate of Purkinje cells was approximately similar for halothane, isoflurane and enflurane (see fig. 7). However, apart from the actions on $GABA_A$ receptors, clinically relevant concentrations of enflurane affected further ionic conductances of Purkinje neurons (figs 12, 13 in Antkowiak and Heck[38]). At 0.5–2.0 MAC these effects considerably changed the discharge patterns of Purkinje cells, but did not alter mean discharge rates. Thus enflurane-induced firing patterns of Purkinje cells and the decrease in the firing rate were caused by different molecular actions of the anaesthetic operating in parallel. At least one of these effects (potentiation of GABA-mediated inhibition) seems to follow the rule, but others do not. This explains why anaesthetic-induced changes in discharge patterns shown in figure 3 are not in accordance with the rule.

Antkowiak and Heck further excluded the fact that increased $GABA_A$-mediated inhibition contributed considerably to depression of firing rates measured at 2–7 MAC.[38] At these high concentrations, the anaesthetic abolished action potential firing of presynaptic GABAergic interneurones and thereby reduced $GABA_A$-mediated synaptic inhibition (figs 6 and 7 in Antkowiak and Heck[38]). At concentrations of 2–7 MAC, further depressant actions come into play.[3] Assuming different mechanisms of anaesthetic action, which contribute to concentration-dependent reduction in average discharge rates, also explains the biphasic nature of the curves in figure 6. It seems possible that activation of potassium channels, as observed in hippocampal, spinal and thalamic neurones, is involved, but other mechanisms, such as block of sodium channels, cannot be excluded.[3]

In conclusion, our results may help to explain why so many studies on brain slices fail to identify mechanisms which follow the Meyer–Overton rule. The latter should not lead to the conclusion that anaesthetic actions, which are in accordance with the rule, do not occur in these preparations. We suggest that effects which are relevant for general anaesthesia and which mediate painful stimuli-evoked motor responses (fig. 1) are frequently masked by side effects. As observed previously, research will have to concentrate on the problem of distinguishing between relevant and side effects.[3] The vast majority of studies concerning the mechanisms that underlie general anaesthesia have been carried out *in vitro*. It is noteworthy, however, that the few *in vivo* investigations available on this topic have reported similar phenomena.[5]

Comparison of the effects of isoflurane with those of propofol on pulmonary vascular impedance in experimental embolic pulmonary hypertension

P. EWALENKO, S. BRIMIOULLE, M. DELCROIX, P. LEJEUNE AND R. NAEIJE

Summary

Inhaled but not i.v. anaesthetics are reported to decrease pulmonary vascular resistance. The aim of this study was to compare the effects of isoflurane with those of propofol on the interaction between right ventricular (RV) function and the pulmonary vascular system in embolic pulmonary hypertension. Nine dogs received in random sequence propofol 18 mg kg^{-1} h^{-1} and 1.4% end-tidal isoflurane. Pulmonary haemodynamic state was evaluated by pulmonary arterial pressure/flow (PAP/$\dot{Q}$) plots and pulmonary vascular impedance (PVZ) spectra. Right ventricular function was assessed by total hydraulic power (*W*tot), ratio of oscillatory power (*W*osc) to *W*tot, and d*P*/d*t*max. Measurements were obtained, with both anaesthetics, before and after pulmonary embolic hypertension induced by autologous blood clots. Embolism increased PAP, 0 Hz and low frequency input impedance, displaced first minimum of PAP/$\dot{Q}$ moduli and zero crossing of phase to higher frequencies, decreased characteristic impedance, decreased *W*osc/*W*tot without affecting *W*tot, and increased d*P*/d*t*max. Compared with propofol, isoflurane at baseline did not affect PAP/$\dot{Q}$ plots, PVZ or hydraulic power data, but decreased d*P*/d*t*max. After embolism, isoflurane shifted PAP/$\dot{Q}$ plots to lower PAP without affecting PVZ, did not affect hydraulic power data and decreased d*P*/d*t*max. We conclude that in canine embolic pulmonary hypertension, isoflurane compared with propofol impeded RV vascular coupling caused by decreased RV contractility, while afterload remained unchanged despite some decrease in pulmonary vascular tone. (*Br. J. Anaesth.* 1997; **79**: 625–630).

Key words
Anaesthetics volatile, isoflurane. Anaesthetics i.v., propofol. Embolism, pulmonary embolism. Cardiorespiratory system, effects. Lung, function.

General anaesthesia is commonly associated with decreased systemic arterial pressure caused by a combination of negative inotropism and vasodilatation. While inhalation and i.v. agents have broadly comparable effects on systemic haemodynamic state, inhaled but not i.v. anaesthetics have been reported to inhibit hypoxic pulmonary vasoconstriction (HPV). This pulmonary vascular effect of inhalation agents is prominent in isolated perfused lung preparations *in vitro*,[1] but less so in more intact animal preparations.[2 3] We reported previously that anaesthesia with inhaled isoflurane compared with i.v. propofol decreased pulmonary vascular tone in hypoxia and hyperoxia, without inhibiting HPV, and that isoflurane-induced pulmonary vasodilatation did not affect pulmonary vascular impedance (PVZ) in intact dogs.[4] However, hypoxia-induced pulmonary hypertension was mild, with pulmonary artery pressure (PAP) seldom exceeding 20 mm Hg,[4] so that the pulmonary vasodilating properties of isoflurane would not be expected to be important. We therefore investigated the pulmonary haemodynamic effects of isoflurane anaesthesia in more severe experimental pulmonary hypertension, such as that induced by autologous blood clot embolization in dogs.

In this study, we characterized the flow-resistive properties of the pulmonary circulation by multipoint mean PAP compared with mean pulmonary blood flow ($\dot{Q}$) relationships, and evaluated right ventricular (RV) afterload by measurement of PVZ. Associated changes in RV function were assessed by the maximum rate of pressure increase (d*P*/d*t*max) and total (*W*tot) and oscillatory (*W*osc) hydraulic power. The measurements were performed before and after induction of autologous blood clot embolism in dogs anaesthetized with either isoflurane or propofol. Propofol was chosen because it does not act as a pulmonary vasodilator[4 5] and because of its very short duration of action, allowing comparisons with isoflurane in the same animal. The hypothesis tested was that isoflurane, despite its negative inotropic properties, would decrease pulmonary vascular resistance (PVR) sufficiently to

decrease ventricular afterload, thereby not altering ventriculo-vascular coupling.

Materials and methods

All experiments were conducted in accordance with the "Guiding Principles in the Care and Use of Animals" approved by the American Physiological Society. We studied 12 mongrel dogs (weight 20–36 kg, mean 27 kg) anaesthetized with propofol 10 mg kg^{-1} i.v. followed, in random order, by either 1.4% end-tidal inhaled isoflurane (=1 MAC for the dog) or propofol 18 mg kg^{-1} h^{-1} i.v. The lungs of the dogs were ventilated with an inspired oxygen fraction ($F_{I_{O_2}}$) of 0.4, 12 bpm and a tidal volume adjusted to maintain arterial P_{CO_2} at approximately 4.66 kPa, and prepared as reported previously.[4] Briefly, femoral and pulmonary arterial catheters were inserted for measurement of systemic and pulmonary haemodynamics and for sampling of arterial and mixed venous blood. Vascular pressures were recorded continuously and read at end-expiration. Cardiac output was measured using the thermodilution method with a fast-response thermistor catheter (93A-131-7.5F, Edwards, Santa Ana, CA, USA) and three injections of 10 ml of ice-cold saline delivered at the beginning of expiration. Cardiac output was controlled by inflating a balloon inserted in the inferior vena cava or by opening a femoral arteriovenous fistula to decrease or increase venous return, respectively.

After 200 ml of blood were obtained for clot formation, sodium heparin 100 u. kg^{-1} was given i.v. to prevent thrombus formation along the catheters. Normal saline was infused at a rate of 10 ml kg^{-1} h^{-1}. Temperature was maintained at 37–38 °C by a heating blanket. A left thoracotomy was performed at the fourth intercostal space. During thoracotomy, $F_{I_{O_2}}$ was increased to 0.6, and 3 cm H_2O of PEEP were applied to maintain adequate gas exchange and prevent atelectasis. Sufentanil boluses of 5–20 μg i.v. were given to provide appropriate analgesia. A non-constricting ultrasonic flow probe was positioned around the pulmonary artery, a manometer-tipped catheter inserted in the pulmonary artery via the RV outflow tract and a second manometer-tipped catheter placed in the RV via the right external jugular vein. Expired isoflurane was monitored with an Ultima respiratory gas analyser (SVi, Meda, Helsinki, Finland).

At the end of surgery, anaesthesia was maintained with the initial anaesthetic agent. After allowing 1 h for stabilization, the first five-point PAP/$\dot{Q}$ plot was generated by measuring PAP and $\dot{Q}$ with the arteriovenous bypass open (one point), then closed (one point), and after stepwise inflation of the inferior vena cava balloon (three points). $\dot{Q}$ and all intravascular pressures were recorded at each step. Arterial and mixed venous blood-gas tensions were measured at the highest and lowest $\dot{Q}$ values. Propofol or isoflurane was then discontinued and anaesthesia resumed with the alternate agent. One hour later, a second PAP/$\dot{Q}$ plot, PVZ data and associated measurements were obtained in a similar way. Embolic pulmonary hypertension was induced over 30 min by injecting blood clots into the jugular vein to reach a PAP of 40–50 mm Hg. Such embolic hypertension stabilizes at 30 mm Hg after 30 min and remains stable for hours.[6] The first three dogs embolized with 1.4% isoflurane anaesthesia died from irreversible cardiac failure before PAP stabilization and were excluded from the study.

In the following isoflurane-anaesthetized dogs, isoflurane was decreased to the lowest concentration compatible with adequate anaesthesia (less than 1%) during and just after embolization, and thereafter reset at 1.4%. After another 30-min period of haemodynamic stabilization, a third PAP/$\dot{Q}$ plot and PVZ data were collected. Anaesthesia was again resumed with the alternate agent, and a fourth PAP/$\dot{Q}$ plot and PVZ data were obtained 1 h later. Each of the nine remaining dogs thus received both anaesthetics before and after embolization. In order to assess the stability of the preparation, care was taken to recover initial post-embolic cardiovascular status and gas exchange variables after generation of each P/$\dot{Q}$ plot until the end of the experiment.

Instantaneous pressure and flow signals were digitized at a rate of 200 Hz, displayed on a monitor screen for visual inspection and stored in a computer. PAP/$\dot{Q}$ plots and PVZ data were analysed as reported previously.[4] Zero flow was adjusted to the end-diastolic plateau of the flow signal. Ultrasonic flow was scaled to the thermodilution value to compensate for ultrasonic underestimation of flow in large vessels,[4] and indexed to body surface area. From PVZ spectra were derived 0 Hz impedance (Z_0), which represents total pulmonary vascular resistance, characteristic impedance (Z_c), first harmonic modulus (Z_1) and phase (Ph_1). Z_c was calculated by averaging P/$\dot{Q}$ moduli between 2 and 10 Hz, and an index of wave reflection, the reflection coefficient (Rc) as $Rc=(Z_0-Z_c) / (Z_0+Z_c)$.[7] *W*tot was computed as the instantaneous pressure–flow product, and *W*osc as the difference between *W*tot and steady power (mean pressure–mean flow product).[7] d*P*/d*t*max was derived from the instantaneous RV pressure wave.

STATISTICAL ANALYSIS

Results are expressed as mean (SEM). Inspection of individual PAP/$\dot{Q}$ plots showed them to be linear and each plot was subjected to linear least square regression analysis. To obtain composite PAP/$\dot{Q}$ plots for each experimental situation, PAP values interpolated from individual regression analysis were averaged at 0.5-litre min^{-1} m^{-2} intervals from 2 to 3.5 litre min^{-1} m^{-2}. Data were analysed by repeated-measures analysis of variance. When the *F* ratio reached $P \leq 0.05$, comparisons were made using modified *t* tests, that is *t* tests calculated with the residual variance of analysis of variance.[8]

Results

MANIPULATIONS OF $\dot{Q}$

Manipulating venous return allowed variations in $\dot{Q}$ of 5.4–1.7 litre min^{-1} m^{-2} (table 1). PAP/$\dot{Q}$

Table 1 Blood-gas tensions and haemodynamic data in nine dogs anaesthetized with isoflurane or propofol, at baseline and after embolism, at the highest and lowest cardiac output. Values (mean (SEM)). relationships appeared linear in all experimental situations with averaged correlation coefficients always greater than 0 9. As embolism was associated with a decrease in $\dot{Q}$ isoflow pulmonary vascular pressures comparisons were limited to $\dot{Q}$ values of 2–3.5 litre min^{-1} m^{-2} (fig. 1). Reducing $\dot{Q}$ was associated with lower arterial P_{O_2} (Pa_{O_2}) and mixed venous P_{O_2} ($P\bar{v}_{O_2}$), no change in arterial P_{CO_2} (Pa_{CO_2}) or in heart rate (HR) (except during isoflurane anaesthesia after embolism), and lower PAP, systemic arterial pressure (SAP), occluded PAP (PAOP) and right atrial pressure (RAP) (table 1).

PULMONARY EMBOLISM

Embolism was associated with a decrease in SAP (after propofol anaesthesia only), Pa_{O_2}, $\dot{Q}$ and increased Pa_{CO_2}, PAP and PAOP, while HR and RAP remained unchanged (table 1) There was an increase in PAP at all levels of $\dot{Q}$ (fig. 1). As determined at the same intermediate value of $\dot{Q}$ of 3 5 litre min^{-1} m^{-2}, embolism was associated with increased Z_0, Z_1, Rc, Ph_1 negativity and d*P*/d*t*max, a shift of the first minimum of impedance moduli to higher frequencies, decreased Z_c and *W*osc/*W*tot, without change in *W*tot (table 2, fig. 2).

COMPARISON OF ANAESTHETIC AGENTS

Before embolism, compared with propofol, isoflurane was associated with a lower HR, SAP and d*P*/d*t*max, but no change in blood-gas tensions, $\dot{Q}$, PAP, PAOP, RAP, Z_0, Z_1, Z_c, Rc, f_{min}, Ph_1, *W*tot or *W*osc/*W*tot (tables 1, 2). Before embolism, PAP/$\dot{Q}$ plots (fig. 1) and PVZ spectra (fig. 2) did not differ.

Table 2 Pulmonary vascular impedance and right ventricular function data in nine dogs anaesthetized with isoflurane or propofol alone, before and after embolism, at the same cardiac output (mean (SEM)). Z_0=0 Hz impedance modulus, Z_1=first harmonic impedance, Z_c=characteristic impedance; Rc=reflection coefficient; f_{min}=frequency of the first minimum; Ph_1=phase angle at the first harmonic; d*P*/d*t*max=maximum rate of increase in ventricular pressure; *W*tot=total hydraulic power; *W*osc=oscillatory power. $^*P<0.05$ embolism *vs* baseline; $\dagger P<0.05$ propofol *vs* isoflurane

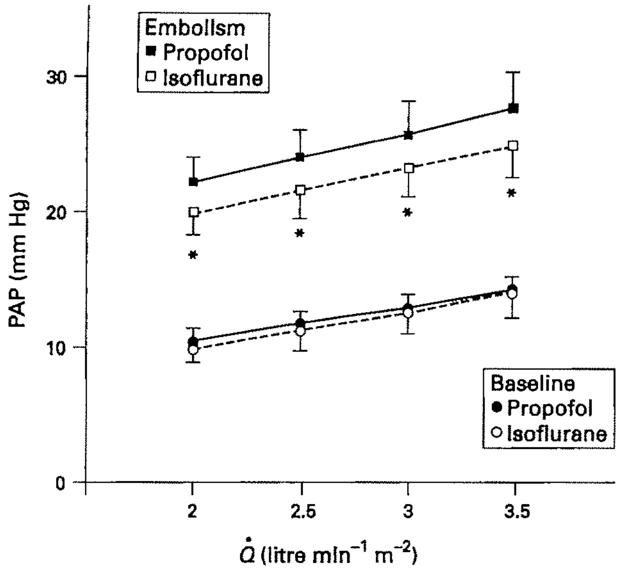

Figure 1 Pulmonary arterial pressure (PAP) *vs* cardiac output ($\dot{Q}$) at baseline and after pulmonary embolism in nine dogs anaesthetized with isoflurane or propofol (mean (SEM)). Embolism was associated with an increase in PAP at all levels of $\dot{Q}$ with both anaesthetics. Before embolism, PAP/$\dot{Q}$ plots did not differ during propofol or isoflurane anaesthesia. After embolism, isoflurane decreased PAP at all levels of $\dot{Q}$. $^{*}P<0.05$ isoflurane *vs* propofol after embolism.

After embolism, isoflurane was associated with a lower HR (except at high $\dot{Q}$), SAP, PAP, dP/dtmax, but no change in blood-gas tensions, $\dot{Q}$, PAOP, RAP, Z_0, Z_1, Z_c, Rc, f_{min}, Ph_1, *W*tot or *W*osc/*W*tot (tables 1, 2). After embolism, isoflurane was associated with a shift in PAP/$\dot{Q}$ plots to lower pressures at all levels of flow (fig. 1) but no difference in PVZ (fig. 2).

Discussion

We have demonstrated that in embolic pulmonary hypertension induced by autologous blood clots, pulmonary vascular tone decreased with isoflurane compared with propofol. However, this decrease was too modest to affect impedance, and RV vascular coupling during isoflurane may deteriorate because of decreased contractility.

ANAESTHETIC DOSE

Although it is difficult to compare inhaled and i.v. anaesthetic agents, we attempted to use equipotent doses of isoflurane and propofol on the basis of the available literature. In dogs, propofol at a rate of 18 mg kg^{-1} h^{-1} is associated with stable plasma concentrations of 5–7 μg ml^{-1}.[5] In acutely instrumented and unstimulated dogs, propofol at a rate of 12 mg kg^{-1} h^{-1} is the minimum rate compatible with adequate anaesthesia[9] and a rate of 30 mg kg^{-1} h^{-1} corresponds approximately to 1.5 MAC of isoflurane.[10] In this study, the depth of anaesthesia appeared comparable with propofol 18 mg kg^{-1} h^{-1} and 1.4 % end-tidal isoflurane (1 MAC for dogs) with regard to noxious stimuli such as reaction to skin incision. Baseline haemodynamic and blood-gas variables were similar with both drugs, with a somewhat lower heart rate and systemic arterial pressure during isoflurane anaesthesia.

NON-PULSATILE HAEMODYNAMICS

We evaluated pulmonary vascular tone by multipoint PAP/$\dot{Q}$ relationships, instead of isolated PVR calculations, to discriminate active from passive

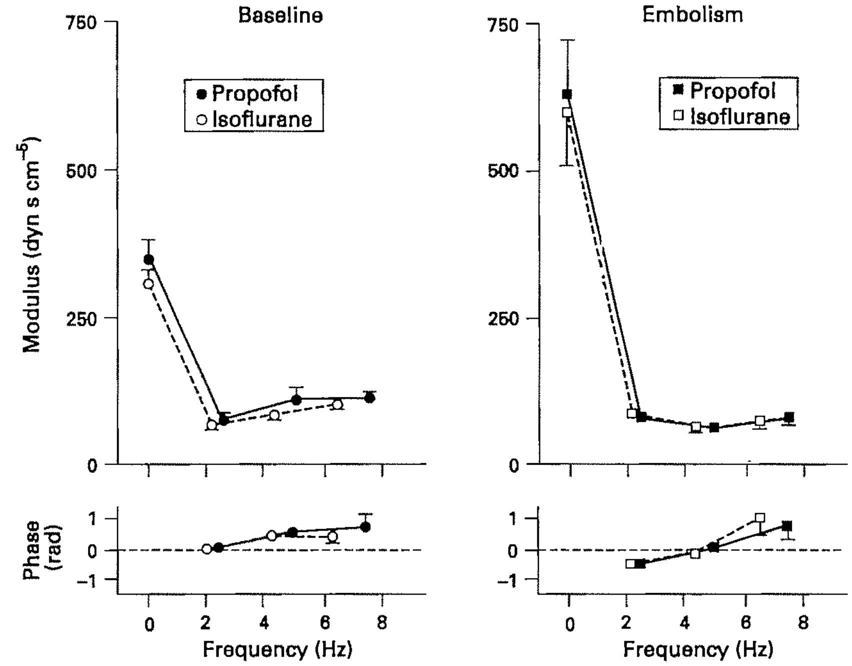

Figure 2 Pulmonary vascular impedance (PVZ) spectra, expressed as ratios of pulmonary artery pressure (PAP) and flow ($\dot{Q}$) moduli, and phase, both compared with frequency at identical intermediate cardiac output values (3.5 litre min^{-1} m^{-2}) before and after embolism (mean (SEM)). Pulmonary embolism increased 0 Hz impedance (Z_0), shifted the first minimum and maximum of PAP/$\dot{Q}$ to higher frequencies, decreased characteristic impedance (Z_c) and shifted the zero crossing of phase to higher frequencies (all $P<0.05$). PVZ spectra were not significantly different for isoflurane or propofol, at baseline or after embolism.

$\dot{Q}$-dependent changes in PAP.[11] We observed parallel upward shifts of PAP/$\dot{Q}$ relationships after embolism. According to the reference Starling resistor model, the extrapolated pressure intercept of PAP/$\dot{Q}$ plots represents the effective outflow pressure of the pulmonary circulation and the slope of PAP/$\dot{Q}$ plots incremental pulmonary vascular resistance.[11] When the extrapolated pressure intercept of PAP/$\dot{Q}$ plots is higher than left atrial pressure (estimated by PAOP), as occurs in experimental pulmonary embolism, this may be explained by the existence of increased vascular closing pressure making left atrial pressure an irrelevant backward pressure in respect of flow.[6 12] However, a distensible vessel model has been reported recently which explains parallel shifts of PAP/$\dot{Q}$ plots to higher pressures after embolism without having to invoke vascular closure.[11 13] Therefore, we did not speculate on the functional significance of slopes and extrapolated pressure intercepts of PAP/$\dot{Q}$ plots in this study. However, our results showed that embolism increased PVR in a $\dot{Q}$-independent manner, and that this change was slightly reversed with isoflurane.

Previous studies that reported minimal or no pulmonary vasodilating effect of isoflurane in various experimental settings[2 3 14 15] included background i.v. anaesthesia with barbiturates. Pentobarbitone anaesthesia alone does not affect PAP/$\dot{Q}$ relationships in hyperoxic sheep lungs[16] or in normoxic intact dogs,[17] but alters autonomic nervous regulation of the pulmonary circulation.[17] Barbiturates may reduce HPV by 14–28% at clinically relevant doses in isolated sheep lungs,[16] but it is not known if this can be extrapolated to intact animals. How background anaesthesia might interfere with the pulmonary vascular effects of isoflurane is uncertain. Comparing isoflurane alone with propofol alone, we reported previously a decrease in pulmonary vascular tone in hyperoxic and hypoxic dogs.[4] In that study, Pa_{O_2} at an FI_{O_2} of 0.4 was consistently lower than in the present experiments, suggesting the presence of low ventilation/perfusion areas, probably related to post-thoracotomy atelectasis, inducing some local hypoxic vasoconstriction that was counteracted with isoflurane. In our study, Pa_{O_2} was preserved better suggesting no lung abnormalities. Baseline PAP/$\dot{Q}$ plots during isoflurane and propofol anaesthesia did not differ, suggesting that isoflurane had no effect on the normally low pulmonary vascular tone. These results concur with those of Lennon and Murray who found similar PAP/$\dot{Q}$ plots in chronically instrumented dogs in the conscious state and during isoflurane anaesthesia.[18]

The pulmonary vascular effects of propofol are not well documented. In pentobarbitone-anaesthetized dogs, propofol did not affect hyperoxic or hypoxic PAP/$\dot{Q}$ plots, before or after cyclooxygenase inhibition.[5] However, in isolated rat aorta and pulmonary arteries, propofol exerted vasorelaxant effects, mediated partly via the cyclooxygenase pathway.[19] Compared with the conscious state, PAP/$\dot{Q}$ plots during propofol anaesthesia might thus be shifted slightly to lower pressures. After embolism, PAP/$\dot{Q}$ plots were shifted to lower pressures with isoflurane compared with propofol. However, this effect was small (a few mm Hg) and equivalent to the vasodilatation observed after hydralazine, isoproterenol and nitroprusside,[6 12] confirming that the functional vasoactive component of increased PVR in embolic pulmonary hypertension is modest and in this case better preserved with propofol than with isoflurane.

PULSATILE HAEMODYNAMICS

In the pulmonary circulation, $\dot{W}$osc is a relatively important fraction of RV external $\dot{W}$tot, which is determined by dynamic interplay between PVR, elastance and wave reflections.[7 11] To evaluate all of the forces that oppose RV ejection, the natural pulsatility of the pulmonary circulation must be taken into account. This is possible by analysis of pressure and flow waves in the frequency domain to calculate PVZ.[7 11] In the present experiments, PVZ spectra before embolism had a classical pattern: a relatively high Z_0 followed by a steep decrease to a minimum of 2–4 Hz, small fluctuations at higher frequencies and a slightly negative phase at lower frequencies.[4 20 21] Milnor, Bergel and Bargainer found no difference in PVZ spectra between awake and halothane-anaesthetized dogs.[21] In our dogs, PVZ spectra were comparable with isoflurane and propofol at baseline. Pulmonary embolism induced by autologous blood clots[22] or 150–200 µm glass beads[20] has been reported to increase Z_0, Z_1, Rc and phase angle negativity, indicating an increase in total pulmonary vascular resistance (Z_0), pulmonary arterial elastance (Z_1) and wave reflection (Rc and phase negativity),[7] and a decrease in Z_c.[20 22] Our results concur. A decrease in Z_c in embolic pulmonary hypertension can be explained by dilatation of the pulmonary arterial tree.[20 22] The characteristic impedance Z_c is the ratio of inertance over compliance of the proximal vessels and varies directly with the elastic modulus of the vessel and indirectly with its cross-sectional area.[7] In our dogs, although isoflow PVR values (evaluated by P/$\dot{Q}$ plots) were lower with isoflurane compared with propofol after embolism, PVZ spectra were not affected differently by anaesthesia. In canine blood clot embolic pulmonary hypertension, Z_c or pulmonary arterial compliance did not change after meclofenamate, ketanserin, atropine or vagotomy.[22] It is thus possible that the only component of PVZ amenable to active neurohumoral control in acute embolic pulmonary hypertension is distal PVR and that isoflurane and propofol might not act differently at conduit (proximal) pulmonary arteries in pulmonary embolism.

RIGHT VENTRICULO-VASCULAR INTERACTION

In the present experiments, baseline RV pressures, $\dot{W}$tot and $\dot{W}$osc/$\dot{W}$tot were comparable with those reported elsewhere.[21 22] Embolism did not affect $\dot{W}$tot and decreased slightly $\dot{W}$osc/$\dot{W}$tot. This also concurs with previous observations.[22] The absence of change in $\dot{W}$tot after embolism may be explained by an increase in wave reflection. This causes pressure and flow waves to become out of phase so that their instantaneous product decreases, as does *W*osc/*W*tot.[22] The latter is beneficial as *W*osc is dissipated in the pulmonary vascular bed and wasteful in terms of blood motion.[7] *W*osc/*W*tot is decreased by an increase in heart rate or a decrease in *Z*c, or both.[21] In this study, since heart rate did not change with embolism, the lower *W*osc/*W*tot was probably related to the decrease in Z_c. At a $\dot{Q}$ value of 3.5 litre $\text{min}^{-1}\ \text{m}^{-2}$, d*P*/d*t*max, a load-dependent index of contractility,[23] was increased after embolism. This allowed only a moderate decrease in $\dot{Q}$ in the face of an increased afterload. At comparable preload and afterload, as evaluated by RAP and PVZ, respectively, d*P*/d*t*max was lower with isoflurane than with propofol. After embolism, lower contractility and lower systemic arterial pressure with isoflurane led to occasional acute right heart failure probably related to impairment of myocardial perfusion, as a consequence of decreased coronary perfusion pressure.[23] Observations made *in vitro* on the isolated ferret myocardium have also demonstrated more important negative inotropic effects of isoflurane compared with propofol at clinically relevant doses.[24 25]

Thus in canine embolic pulmonary hypertension, compared with propofol, isoflurane caused deterioration in RV arterial coupling by a decrease in myocardial contractility, whereas RV afterload evaluated by PVZ was not decreased, despite a small reduction in pulmonary vascular tone evaluated by PAP/$\dot{Q}$ plots.

Extra-pulmonary effects of inhaled nitric oxide in swine with and without phenylephrine

E. TRONCY, M. FRANCŒUR, I. SALAZKIN, F. YANG, M. CHARBONNEAU, G. LECLERC, P. VINAY AND G. BLAISE

Summary

We have compared the effects of inhaled nitric oxide (iNO) and i.v. nitroglycerin (ivGTN) on the haemodynamic response to phenylephrine-induced hypertension (PEHT) in anaesthetized pigs. PEHT did not change either pulmonary vascular resistance or gas exchange throughout all experiments. Both treatments lowered pulmonary arterial pressure to the same extent (−12.4% iNO; −13.7% ivGTN) and passively via an effect on left atrial pressure (−26.3% iNO; −31.4% ivGTN). Both treatments failed to reverse the decrease in renal blood flow (RBFc) induced by PEHT, but both increased urinary flow (UF) (+128% iNO; +148% ivGTN). IvGTN significantly increased plasma concentrations of nitrite and nitrate during (+22.7% arterial blood; +26.2% venous blood) and beyond the period of infusion (iNO: +6.4% and +4.9%, respectively). In four control pigs (no PEHT), iNO markedly increased RBFc (+109%), glomerular filtration rate (+72.5%) and UF (+68.7%). We conclude that iNO may have direct cardiac and renal effects, probably via intervention of NO carrier forms such as *S*-nitroso compounds. (*Br. J. Anaesth.* 1997; **79**: 631–640).

Gases non-anaesthetic, nitric oxide. Pharmacology, nitric oxide. Pharmacology, nitroglycerin. Sympathetic nervous system, phenylephrine. Pig. Kidney, function. Kidney, diuresis.

I.v. endothelium-independent nitrovasodilators such as sodium nitroprusside and nitroglycerin (ivGTN) produce their vasodilator effects by providing nitric oxide.[1] In contrast with i.v. medication, inhaled nitric oxide (iNO) is used commonly as a selective pulmonary vasodilator in experimental[2] and clinical[3] conditions. Inhaled NO is "microselective" in that it dilates only vessels directly adjacent to the alveolar units being ventilated. Therefore, in a hypoxaemic patient, iNO may improve oxygenation by improving ventilation/perfusion matching with redistribution of blood flow from unventilated shunted areas to ventilated but underperfused areas.[4] Some authors also explain the improved oxygenation with iNO by the fact that it produces local bronchodilation,[2 4] decreases vascular permeability and the appearance of pressure-driven pulmonary oedema,[4] and exerts a platelet anti-aggregating effect.[2]

A swine model has been used in the past to study the treatment of experimental pulmonary hypertension induced by hypoxia,[5] a thromboxane analogue,[6] oleic acid-induced ARDS[7] or sepsis.[2 4] Phenylephrine is a sympathomimetic amine commonly used in *in vitro* studies of the L-arginine:NO pathway[8] or to counteract clinical hypotension.[9] We have developed a phenylephrine-induced hypertension (PEHT) model in anaesthetized pigs. We wished to test the hypothesis that iNO does not affect the systemic circulation. Accordingly, we compared the effects of iNO and ivGTN on pulmonary and systemic haemodynamics and gas exchange, in addition to plasma and urinary concentrations of nitrite (NO_2^-) and nitrate (NO_3^-), stable metabolites of nitrogen oxides and related species (NO_xs), that is pNO_x^- and uNO_x^-, respectively. In order to evaluate potential extra-pulmonary effects of iNO, we have compared the effects of iNO and ivGTN on diuresis and renal haemodynamics in pigs in the presence or absence of PEHT.

Materials and methods

This study was approved by the Institutional Research and Animal Welfare Committee. The animals were treated according to the Canadian Council on Animal Care guidelines. We studied 28 female pigs, mean weight 22.84 (SEM 0.27) kg.

The pigs were premedicated with azaperone 2 mg kg^{-1} i.m., ketamine 15 mg kg^{-1} i.m. and atropine 4 μg kg^{-1} i.m. After induction of anaesthesia with fentanyl 5 μg kg^{-1} i.v. and pentobarbitone 6.5 mg kg^{-1} i.v., the trachea was intubated and the lungs ventilated using a volume-controlled ventilator (Ventilator 7200 AE, Puritan Bennett, Carlsbad,

Accepted for publication: June 25, 1997.

CA, USA). Tidal volume was set at 15 ml kg^{-1}, $F_{I_{O_2}}$ at 0.30 (Oxygen Monitor 5590, Hudson RCI, Temecula, CA, USA) and ventilatory frequency adjusted to maintain the partial pressure of arterial carbon dioxide (Pa_{CO_2}) at 4.6–6.0 kPa (Blood gases analyser IL 1620, Coulter Electronics Ltd, Ville Saint-Laurent, Qc, Canada). Anaesthesia was maintained with continuous infusion of fentanyl 3.8 μg kg^{-1} h^{-1} and pentobarbitone 9.8 mg kg^{-1} h^{-1}. Neuromuscular block was produced with a mixture of tubocurarine 0.2 mg kg^{-1} h^{-1} and pancuronium 0.15 mg kg^{-1} h^{-1}. Lactated Ringer's solution was infused at a rate of 15 ml kg^{-1} h^{-1} to meet maintenance needs during open-chest surgery.

After placing the electrocardiographic leads, we inserted an arterial pressure catheter (carotid artery), two venous infusion cannulae (external jugular vein, auricular vein), a pulmonary artery thermodilution catheter (for cardiac output), a core temperature probe and central venous catheter. Median sternotomy was performed, the pericardium opened and two catheters (12-gauge) inserted, one into the main pulmonary artery and the other into the left atrial appendage for pressure monitoring in addition to arterial and venous blood sampling for blood-gas analysis. The pericardium and chest wall were closed with sutures and metallic wires. Via a laparotomy, the left renal vein (renal venous blood sampling site) and both ureters were catheterized, and the left ovarian vein was ligated because of drainage into the renal vein. After instrumentation, 45 min were allowed to elapse to obtain a stable physiological state.

Each experiment was divided into four stages (I–IV) of 20 min (table 1). Animals were enrolled in the experiments in random order.

Control arm. In control studies we evaluated the effect of time (experiment A), PEHT alone (experiment B) and iNO alone (experiment C).

Experimental arm. The four stages in the experiments were: (I) baseline measurements, (II) induction of PEHT by continuous infusion of phenylephrine diluted in saline (mean 14.68 (SEM 1.36) μg kg^{-1} min^{-1}), (III) intervention to treat PEHT with an infusion of ivGTN (experiment D) or 40 ppm of iNO (experiment E), and (IV) a recovery period where both the hypertensive stimulus and treatment were discontinued.

ADMINISTRATION OF IVGTN

The dose of ivGTN (Nitroject, Omega Laboratories Ltd, Montréal, Qc, Canada) was started at 10 μg kg^{-1} min^{-1} and increased progressively (3-min interval) to reduce mean pulmonary arterial pressure to the level observed after iNO. The period of measurement (stage III) was then started. The mean final dose of ivGTN used in experiment D was 92.43 (SEM 13.45) μg kg^{-1} min^{-1}.

ADMINISTRATION OF INO

A mixture of NO–N_2 972 ppm (Cylinder NO 972 ppm, <5 ppm of NO_2, Vitalaire Canada, Montréal, Qc, Canada) was injected cyclically into the inspiratory limb of the ventilator system using a method developed in our institution.[10] Concentrations of gaseous NO and NO_xs were monitored continuously using a chemiluminescence analyser (CLD700AL NO/NO_x analyser, Ecophysics Tecan AG, Dürten, Switzerland). Based on our previous work,[5 6] we chose to study the effects of iNO 40 ppm. This dose was shown in several studies[3–7] to have a significant pulmonary vasodilator effect while ensuring an inspired fraction of NO_2 below 1 ppm with our system.[10]

RENAL MONITORING

Thirty minutes before the beginning of baseline measurements (stage I), a bolus of inulin 2 g and para-amino-hippuric acid (PAH) 2 g dissolved in 50 ml of glucose were administered, immediately followed by an infusion of inulin 2 g and PAH 4 g dissolved in 1000 ml of glucose at a constant rate of 1 ml min^{-1}. Blood samples (4 ml) were obtained simultaneously from the left renal vein and carotid artery in order to measure packed cell volume (PCV), PAH and inulin concentrations, in addition to arterial and venous pNO_x^- concentrations. Blood samples were collected at the beginning of stage I and at the end of each 20-min period. Urine was collected separately in graduated cylinders from both ureters at 5-min interval during the whole procedure to measure urinary flow (UF), PAH and inulin concentrations, and uNO_x^-. The concentration of PAH in both urine and blood was measured using the technique described by Bratton and Marshall.[11] Renal plasma flow (RPF) was taken as PAH clearance ($Cl_{PAH}=C_u \times (UF/C_a)$, where C_u=PAH concentration in urine and C_a=PAH concentration in arterial blood plasma). Renal plasma flow was corrected (RPFc) for PAH extraction coefficient

Table 1 Study design. *No intervention. †PE=Phenylephrine infusion at mean 15.75 (SEM 0.85) μg kg^{-1} min^{-1}; ‡PE=phenylephrine infusion at 14.68 (1.36) μg kg^{-1} min^{-1}; iNO=inhaled nitric oxide 40 ppm; ivGTN=nitroglycerine infusion at 92.43 (13.45) μg kg^{-1} min^{-1}

		Stage and time

Control	A	Nil*	Nil	Nil	Nil	n=4
	B	Nil	PE†	PE†	Nil	n=4
	C	Nil	iNO	iNO	Nil	n=4
Experimental	D	Nil	PE‡	PE‡-ivGTN	Nil	n=8
	E	Nil	PE‡	PE‡-iNO	Nil	n=8

($E_{PAH}=(C_a-C_v)/C_a$, where C_v=PAH concentration in renal vein blood plasma), and renal blood flow corrected for PAH extraction (RBFc) was taken as RPFc/(1−PCV). Because PAH acetylation was observed with some pigs, RBFc was calculated for each 5-min interval using PAH and inulin clearances and extractions. Inulin concentration was measured by an anthrone colorometric technique,[12] and whole kidney glomerular filtration rate (GFR) was calculated for each 5-min interval by the standard clearance formula.

MEASUREMENTS OF PNO_x^- AND UNO_x^-

Plasma samples obtained by centrifugation were diluted 10-fold with distilled water and deproteinized by adding 5% volume of zinc sulphate to a final concentration of 15 g litre^{-1}.[13] After centrifugation at 1000×*g* for 15 min at room temperature, 100 μl of supernatant were applied to a microreaction purge vessel chamber (270B NO analyser, Sievers Research Inc, Boulder, CO, USA) equipped with a temperature regulator and a condenser, which allowed direct introduction of prepared plasma and urine samples into the reducing solution. pNO_x^- and uNO_x^- concentrations were measured by conversion to NO using hot acidic vanadium (III) chloride. NO was eluted in a stream of nitrogen and detected by an ozone-induced chemiluminescence reaction. The NO/NO_x analyser was connected directly to a data acquisition system (Mac Lab, Lamont Scientific Ltd., Downsview, Ont, Canada). Each sample was analysed in duplicate and measured once at the end of each 20-min period, as described previously.[13]

CARDIORESPIRATORY VARIABLES

Systolic (SAP), mean (MAP) and diastolic (DAP) systemic arterial pressures, mean pulmonary arterial pressure (PAP), left atrial pressure (LAP), central venous pressure (CVP), heart rate (HR) and cardiac output (CO; 5 ml of cold normal saline were injected in triplicate for each measurement) were recorded every 5 min in each period. Arterial and mixed venous blood-gas tensions were measured once at the end of each 20-min period.

DATA ANALYSIS

In the control arm, the sample size was $n=4$ for each experiment (table 1). In the experimental arm, the sample size was $n=8$ for each experiment. Half of the pigs in experiments D and E were used to evaluate renal effects and the other half to measure pNO_x^- and uNO_x^- concentrations.

Data distribution of each variable was Gaussian. For each stage, mean values of four measurements (obtained every 5 min) or a single measurement (obtained only once during each stage) were chosen as the values for the period. Pulmonary (PVR) and systemic (SVR) vascular resistances were calculated using standard formulae. All values are reported as mean (SEM) for each variable in each stage (I–IV) of the experiments.

Data were analysed using SuperANOVA (V 1.11, Abacus Concepts Inc. 1989/1991, Berkeley, CA, USA) and SAS (Statistical Analysis System V6.11 for Windows 95, SAS Institute Inc. 1995, Cary, NC, USA) software.

For each experiment, the effect of stage was evaluated with the one-factor repeated measures analysis of variance (F-ANOVA) and, when necessary, multiple comparisons were made using Fisher's protected least significant difference (LSD_F) test.

Between the five experiments, for the difference between two stages (e.g. stages-difference

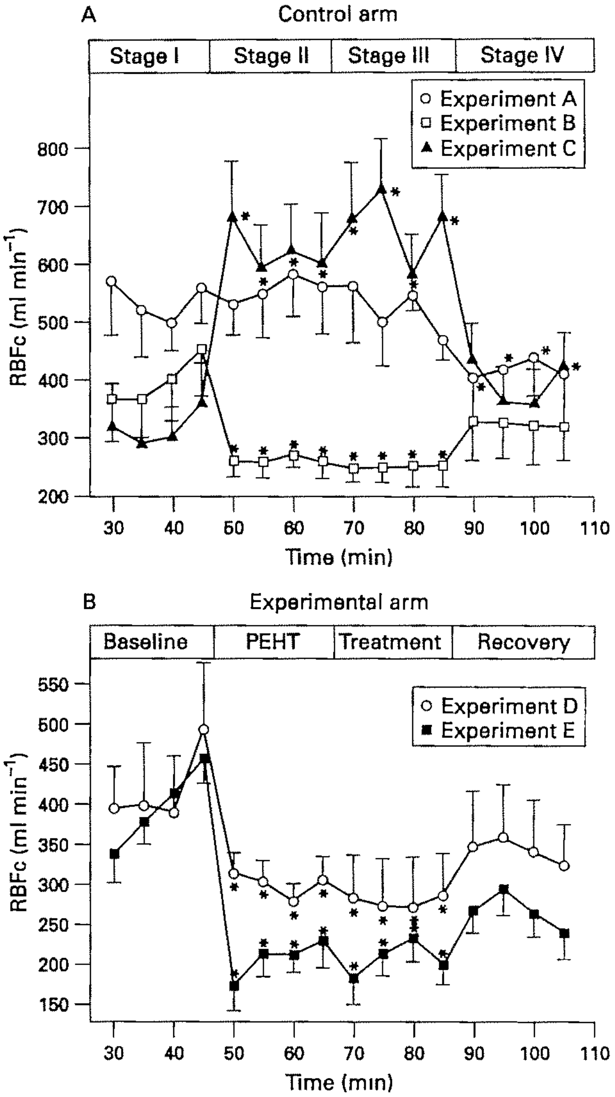

Figure 1 Variation in renal blood flow corrected for PAH extraction (RBFc). A. Control arm: mean (SEM) values for RBFc for each sampling time in each stage (I–IV) for experiment A (no intervention during the four stages), experiment B (infusion of phenylephrine 15.75 (0.85) μg kg^{-1} min^{-1} during stages II and III), and experiment C (iNO 40 ppm during stages II and III). RBFc decreased with time in experiment A. Infusion of phenylephrine significantly reduced RBFc while iNO considerably increased RBFc. *Significant difference for F-ANOVA (P<0.05) and for the LSD_F test of the stage compared with stage I (P<0.008). B: Experimental arm. mean (SEM) values for RBFc for each sampling time in each stage (I–IV) for experiment D (PEHT+ivGTN treatment) and experiment E (PEHT+iNO treatment). Infusion of phenylephrine significantly reduced RBFc and nitrergic treatments failed to reverse the decrease.*Significant difference for F-ANOVA (P<0.05) and for the LSD_F test of the stage compared with stage I (P<0.008). (See text for further details.)

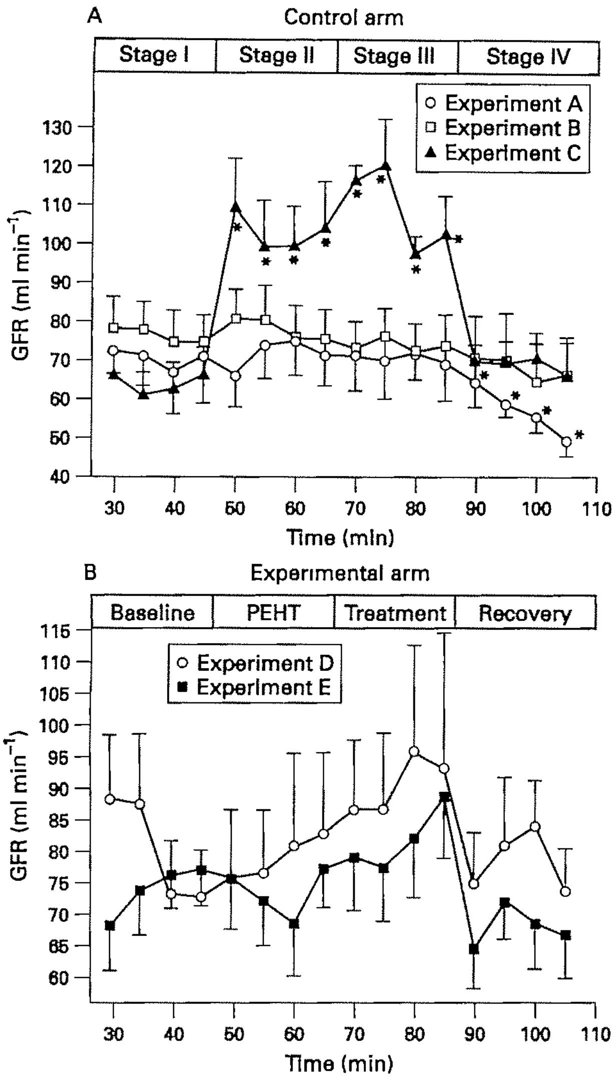

Figure 2 Variation in glomerular filtration rate (GFR). A: Control arm: mean (SEM) values for GFR for each sampling time in each stage (I–IV) for experiment A (no intervention during the four stages), experiment B (infusion of phenylephrine 15.75 (0.85) $\mu g\ kg^{-1}\ min^{-1}$ during stages II and III), and experiment C (iNO 40 ppm during stages II and III). GFR decreased with time in experiment A. Infusion of phenylephrine had no effect on GFR while iNO considerably increased GFR. *Significant difference for F-ANOVA ($P<0.05$) and for the LSD_F test of the stage compared with stage I ($P<0.008$). B: Experimental arm: mean (SEM) values for GFR for each sampling time in each stage (I–IV) for experiment D (PEHT+ivGTN treatment) and experiment E (PEHT+iNO treatment). Infusion of phenylephrine and nitrergic treatments did not modify GFR. (See text for further details.)

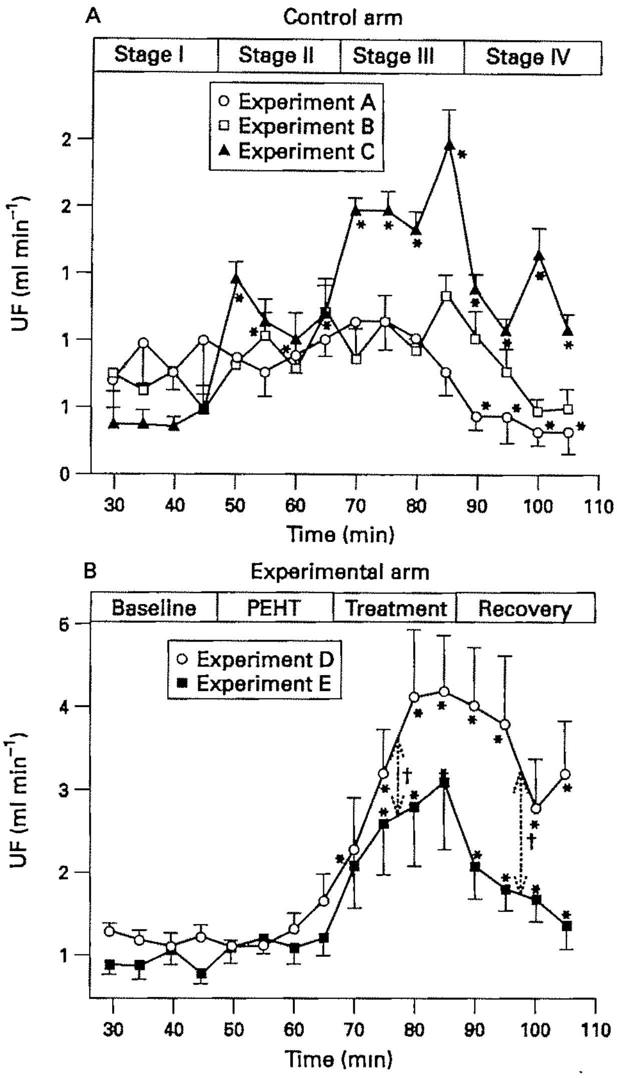

Figure 3 Variation in urinary flow (UF). A: Control arm: mean (SEM) values for UF for each sampling time in each stage (I–IV) for experiment A (no intervention during the four stages), experiment B (infusion of phenylephrine 15.75 (0.85) $\mu g\ kg^{-1}\ min^{-1}$ during stages II and III), and experiment C (iNO 40 ppm during stages II and III). UF decreased with time in experiment A. Infusion of phenylephrine had no effect on UF while iNO considerably increased UF. *Significant difference for F-ANOVA ($P<0.05$) and for the LSD_F test of the stage compared with stage I ($P<0.008$). B: Experimental arm: mean (SEM) values for UF for each sampling time in each stage (I–IV) for experiment D (PEHT+ivGTN treatment) and experiment E (PEHT+iNO treatment). Infusion of phenylephrine did not modify UF and both nitrergic treatments significantly increased UF, ivGTN more than iNO. *Significant difference for F-ANOVA ($P<0.05$) and for the LSD_F test of the stage compared with stage I ($P<0.008$). †Significant difference between groups for W-ANOVA ($P<0.05$) and for the LSD_W test ($P<0.005$) on the difference (III–II) and (IV–III). (See text for further details.)

(III–I)=between stages III and I), one-way analysis of variance (W-ANOVA) was used and multiple comparisons were made using Fisher's protected least significant difference (LSD_W) test.

$P<0.05$ was considered significant, except for multiple comparisons where the global significance level of 0.05 was adjusted for the number of null hypotheses tested ($P<0.008$ for multiple comparisons within group LSD_F and $P<0.005$ for multiple comparisons between the five groups LSD_W).

Results

For each experiment, the cardiovascular, renal and metabolic (pNO_x^-, uNO_x^-) effects observed during each stage are presented.

CONTROL ARM

In experiment A on the effect of time, there was no change in the measured variables, except for a decrease in renal haemodynamics and diuresis: stage IV was different from the three preceding periods for RBFc (−22.9%; fig. 1A), GFR (−20.8%; fig. 2A) and UF (−19.5%, fig. 3A).

Table 2 Effects of phenylephrine (PEHT) and its treatment by inhaled NO (iNO) or i.v. nitroglycerin (ivGTN) on pulmonary and systemic haemodynamic variables (mean (SEM) in anaesthetized pigs. [III–II]=Mean (SEM) values of the percentage variation between stages III (treatment) and II (PEHT). *P value <α; †P value of the one-factor repeated measures analysis of variance for the within-group analysis on the four periods was not significant. P_1=P value of Fisher's protected LSD_F test for comparison of stages II and III within group (α=0.008); P_2=P value of Fisher's protected LSD_W test for comparison of the difference [III–II] between groups (α=0.005)

During experiment B, phenylephrine significantly increased PAP by 40% (LSD_F comparison of stage II with stage I: P=0.0001), but PVR remained unchanged (F-ANOVA: P=0.42). PEHT significantly increased MAP and SVR: +65.9% and +64.5%, respectively. LAP and CVP exhibited similar changes: +67.9% and +49%, respectively. Phenylephrine had no effect on HR or CO (F-ANOVA, P=0.17 and P=0.33, respectively). The haemodynamic changes were stable during stage III. Compared with stage I, phenylephrine induced a similar decrease in RBFc for stage II (−34%, LSD_F: P=0.001) (fig. 1A) and III (−37%, LSD_F: P=0.001) (fig. 1A) but other renal variables remained unchanged (figs 2A and 3A). The vasoconstrictor did not significantly modify arterial (92.6 (4) to 96 (5.1) µmol litre^{-1}) or venous (89.8 (5.5) to 94.1 (8.3) µmol litre^{-1}) pNO_x^- or uNO_x^- (988.2 (73.4) to 1132.4 (102.6) µmol litre^{-1}) concentrations.

In experiment C, iNO alone did not significantly alter cardiorespiratory variables. However, renal function was affected: RBFc increased by +94% (LSD_F: P=0.0046) (fig. 1A), GFR by +63% (LSD_F: P=0.0001) (fig. 2A) and UF by +34% (LSD_F: P=0.006) (fig. 3A) during stage II; the changes in the three variables remained constant during stage III (+109%, +72.5% and +68.7%, respectively) (figs 1A–3A). UF remained high during stage IV (LSD_F:

$P=0.001$ compared with stage I) (fig. 3A). The concentration of pNO_x^- was slightly modified by iNO in arterial (109.2 (3.1) to 119.8 (3.3) μmol litre^{-1}) and venous (116.4 (4.7) to 124.3 (4.8) μmol litre^{-1}) blood, and uNO_x^- increased from 691.2 (113.8) to 1011.3 (157.3) μmol litre^{-1} during stage II. ΔpNO_x^- increased continually during stage III compared with stage I (+22.1 and +21.4 μmol litre^{-1} in arterial and venous blood), and decreased on cessation of iNO. The value of uNO_x^- remained at the same high level during stages III and IV.

EXPERIMENTAL ARM

Infusion of phenylephrine in experiments D and E produced the same cardiovascular (table 2), renal (fig. 1B–3B) and metabolic (table 3) effects as in experiment B (W-ANOVA: $P>0.1$ on difference (II–I) between experiments B, D and E).

Both nitrergic treatments decreased LAP (−31.4% ivGTN group=experiment D; −26.3% iNO group=experiment E) and CVP (−25.7% and −19.1%, respectively), achieving the same stages-difference (III–II) between experiments D and E (LSD$_W$: $P=0.1$ for LAP and $P=0.09$ for CVP) (table 2). The effect on pulmonary hypertension was the same in both groups (table 2): PAP decreased by 13.7% and 12.4%, respectively. IvGTN decreased MAP (−39.4%) and SVR (−49.3%), and iNO induced a much smaller decrease in systemic haemodynamic variables (table 2). HR, CO and blood-gas values remained unchanged throughout the experiment.

The two nitrergic treatments did not reverse the decrease in RBFc induced by phenylephrine (fig. 1B), but they both increased UF (+148%, LSD$_F$: $P=0.0005$ for experiment D; +128%, LSD$_F$: $P=0.0004$ for experiment E) (fig. 3B). Comparison between experiments D and E on stages-difference (III–II) showed that ivGTN exerted more effect on UF than iNO (LSD$_W$: $P=0.003$). Infusion of ivGTN increased pNO_x^- concentrations compared with stage II (table 3): +22.8% for arterial blood and +26.2% for venous blood. The values in experiment E were +6.4% and +4.9% for arterial and venous blood, respectively (table 3). Both nitrergic treatments markedly increased uNO_x^- concentrations (+65.4% for experiment D and +46.3% for experiment E).

At the end of the experiment, cardiovascular, respiratory and renal (except for UF in experiments D and E (LSD$_F$: $P=0.001$ for comparison of stages IV to equivalent stages I; fig. 3B) variables essentially returned to their initial values. In experiment D, the increases in arterial and venous pNO_x^- (table 3) and uNO_x^- concentrations observed during stage III were still present during stage IV. Twenty minutes after cessation of iNO, pNO_x^- concentration significantly decreased (compared with stage III) in experiment E (table 3), whereas uNO_x^- remained high (1206.4 (108.9) μmol litre^{-1}). Comparison between experiments D and E on stages-differences (IV–III) and (IV–I) confirmed that pNO_x^- returned to baseline values in the iNO group but not in the ivGTN group.

Discussion

To our knowledge, this is the first report of PEHT in swine treated with nitrergic therapies and the first study of the haemodynamic extra-pulmonary effects of iNO.

The model used in these studies is well established. There was no mortality during the surgical preparations and we demonstrated with experiment A that cardiorespiratory variables remained stable during the period of the study and there were only minimal changes in renal function.

EXPERIMENT B

Cardiovascular effects

Phenylephrine acts on both α_1- and α_2-adrenoceptors[14] and induces hypertension (major α_1-effect) by constricting resistance and, to a lesser degree, capacitance vessels.[9] We observed no signs of tachyphylaxis with phenylephrine during the experiments. The observed passive post-capillary pulmonary hypertension with increased central filling pressures was secondary to the left ventricular haemodynamic effects of the acute increase in afterload induced by systemic hypertension. During the experiment, PVR did not change, in agreement with heterogenous[15] α-adrenergic innervation of large (5–7 mm in diameter) and small (2–3 mm in diameter) porcine pulmonary arteries and sparse or non-existant[16] α-adrenergic innervation of swine pulmonary resistance vessels.

Renal effects

The kidney reacted to phenylephrine-induced increase in SVR by a decrease in RBFc,[9] while GFR and UF remained unchanged. This suggests that phenylephrine constricted mainly the efferent arteriole and that GFR was maintained, despite a decrease in RBFc, by an increase in glomerular filtration fraction.[17]

Metabolic effects

The baseline values of pNO_x^- were higher than those measured in a porcine model of ARDS (30 μmol litre^{-1}).[7] However, the measurement techniques were different (chemiluminescence *vs* high-pressure liquid chromatography based on the Griess reaction[7]) and the surgical stress of our procedure may have stimulated release of endogenous NO. Furthermore, reported values for basal concentrations of pNO_x^- (mainly NO_3^-) in humans vary greatly.[18–20] Our basal values for uNO_x^- were in accordance with those published previously in humans.[18 20]

EXPERIMENT C

Inhaled NO alone induced no cardiorespiratory modifications, but considerably altered renal function.

Transport of EDRF–NO

Several authors have suggested that EDRF–NO interacts with circulating molecules to regulate its activity, allowing its transport (NO carriers)[21 22] or promoting its degradation (NO scavengers).[23] Metal nitrosylation with haem and non-haem proteins and the NO reaction with nucleophil groups (e.g. sulfhydryl, amine)[24] of amino acids, peptides and proteins lead to the potential interaction and formation of many nitrosyl–haem adducts, *S*-non-protein-nitrosothiols (*S*-nitroso-L-cysteine), *S*-nitrosylated proteins (*S*-nitrosoalbumins,[21] *S*-nitrosohaemoglobins[22 23]), nitrosylated iron–sulphur clusters, dinitrosyl–iron complexes,[25] nitrosoamines and others.

Renal effects

Renal haemodynamics and diuresis were altered by iNO (experiment C), strongly supporting the presence of extra-pulmonary effects. It is now widely accepted that EDRF–NO is an important modulator of RBF and that regional microcirculation[26] may be mediated by endogenously produced EDRF–NO. Pharmacological block of EDRF–NO results in an increase in MAP and renal vascular resistance, and decrements in RBF, GFR, UF and sodium excretion.[27] There is some controversy regarding a selective effect of EDRF–NO block on either afferent or efferent arteriolar tone.[26] It would seem that EDRF–NO primarily alters afferent vascular tone,[28] thereby modifying the ability of the preglomerular vasculature to autoregulate glomerular capillary pressure. Several studies have emphasized an effect of EDRF–NO not only on glomerular but also on tubular function and the medullary circulation.[28 29] McKee, Scavone and Nathanson[30] showed that EDRF–NO, through generation of cGMP and stimulation of cGMP-dependent protein kinase(s), mediates the actions of several intercellular messengers to regulate renal tubular Na–K-ATPase. Inhibition of this sodium pump (e.g. by acetylcholine, bradykinin) would decrease transcellular water and sodium reabsorption from the tubular lumen, resulting in diuresis and natriuresis. Moreover, low doses of NO synthase inhibitors, that have no effect on either RBF or GFR, induce antidiuretic and antinatriuretic effects.[31] Here is the first report of exogenous iNO modulating renal function. Renal haemodynamic state may be influenced during iNO administration by circulating NO metabolites (e.g. NO_x^-),[32] renal NO delivery through release from carrier *S*-nitroso compounds (e.g. *S*-nitrosothiols)[33] after nitrosylation in the pulmonary circulation, or a local renal effect owing to an unknown paracrine influence stimulated by iNO. *In vitro* studies have shown that $NaNO_2$ did not influence renovascular tone in concentrations up to 0.1 mmol litre^{-1}.[33] The diuretic effect of $NaNO_3$ was observed with a plasma NO_3^- concentration of 38 mmol litre^{-1} in dogs.[32] In view of the rapid renal response to application and discontinuation of iNO, we postulate that iNO may be accompanied by non-selective, extra-pulmonary effects caused by local delivery of NO on peripheral territories that include the renal bed.

Metabolic effects

Nitric oxide reaching the circulation can be metabolized via three pathways:[23] (i) interaction with dissolved oxygen in blood to form NO_2^-, (ii) reaction with oxyhaemoglobin to form methaemoglobin which in turn is reduced back to haemoglobin and NO_3^- mainly by the NADPH–methaemoglobin reductase and peroxynitrite pathways, and (iii) combination with deoxyhaemoglobin to form the stable nitrosohaemoglobin (HbNO) or with carrier molecules to form *S*-nitrosothiols among others (see above). However, to date, the mechanisms by which NO is inactivated and eliminated are not fully known.

The concentration of pNO_x^- increased almost linearly throughout inhalation, and decreased on cessation of iNO. This result is in agreement with those of previous reports[19 20] which have shown a linear temporal increase in pNO_x^-. Approximately 40 μmol of uNO_x^- were excreted in urine during the 40-min inhalation period, a result similar to that of Wennmalm and colleagues,[19] and the rate of elimination was maintained over the following 20 min. This implies that 23.6% of the retained NO was excreted in urine as uNO_x^- within 1 h after the start of inhalation. This early and fast elimination of iNO corroborates a previous study[20] that showed 69% of inhaled ^{15}NO was excreted in urine as $^{15}NO_3^-$ within 24 h and another 4% from 24 to 48 h after the start of inhalation. Moreover, the decrease in pNO_x^- and maintenance of diuresis and high uNO_x^- concentrations after cessation of iNO suggest that NO_x is stored in packaged forms before its release without vasoactive but with diuretic effects, transformation and elimination as NO_x^-.

EXPERIMENTAL ARM

Cardiovascular effects

Inhaled and i.v. nitrergic treatments partially reversed the passive pulmonary hypertension induced by phenylephrine. With the PEHT swine model, iNO 40 ppm was less effective in reducing PAP (50% reversal of the increase) than during hypoxia (108.7% at 40 ppm),[5] thromboxane-mimetic infusion (61% at 40 ppm),[6] experimental ARDS (57.1% at 40 ppm)[7] or sepsis (84% at 10 ppm;[2] 64.8% at 40 ppm[4]). PVR remained unchanged throughout the experiment suggesting that the pulmonary resistance vasculature was not constricted and that both treatments did not act at this level in the PEHT swine model. Because the pulmonary vascular tone was unchanged by nitrergic treatments superimposed on PEHT, baseline gas exchange variables also remained unchanged.

The increase in PAP induced by phenylephrine was adjusted to comparable levels in both groups. Both treatments induced similar decreases in LAP, and consequently PAP and CVP. The decrease in LAP may be explained by a decrease in left atrial filling, increase in left compliance, decrease in left ventricular afterload or a combination of these effects. The first hypothesis is unlikely because CO did not change and there was no clinical sign of an increase in lung water as gas exchange variables remained constant. The second assumption implies, from the formed cGMP,[1] block of α_1 effects on cardiac contraction and relaxation,[34] and a positive lusitropic effect increasing relaxation and diastolic distensibility of the heart.[35] A direct cardiac effect of endothelium-independent nitrovasodilators, such as depressed myocardial contractility,[36] improved ventricular relaxation and diastolic distensibility[37] is accepted. The decrease in systemic afterload (third postulate) was manifest with ivGTN infusion which induced a substantial decrease in SVR. An endogenous EDRF–NO signalling pathway has been found to regulate cardiac myocyte function.[38] The paracrine actions of EDRF–NO stimulated by substance P or bradykinin, particularly on left ventricular relaxation, are also well established.[39] The second and third hypotheses imply extrapulmonary effects with iNO. In a previous study,[5] we suggested that iNO had a direct cardiac effect. There was a slight modification of left ventricular afterload with iNO, as the observed decreases in SAP and MAP were statistically significant (LSD_F: $P=0.0001$ and $P=0.004$, respectively) (table 2). We propose that iNO had a direct cardiac effect to explain the similar action of ivGTN and iNO on PAP, LAP and CVP. Our data indicate a larger decrease in SAP and MAP than that for DAP, suggesting that factors other than aortic compliance or SVR are modified by iNO. These other factors are usually related to changes in the mechanical performance of the heart as a pump.[40] A trend for iNO to decrease SVR or MAP was observed in several publications.[2,3,7].

Renal effects

In experiments D and E, nitrergic treatments superimposed on phenylephrine infusion resulted in increases in UF without reversing the phenylephrine-induced decrease in RBFc. The primary phenylephrine site of action in the kidney seems to be the efferent arteriole in contrast with the afferent arteriole for EDRF–NO. This could explain the lack of reversibility for the decrease in RBFc induced by phenylephrine for both nitrergic treatments. Our findings also support a direct diuretic (and natriuretic?) effect of exogenous NO. Another hypothesis is the involvement of regulatory systems, either intrarenal such as the kallikrein–kinin system or prostaglandins (PGE_2), or extrarenal such as atrial natriuretic factor (ANF) or the oubain-like endogenous factor that increase diuresis.[41] However, EDRF–NO released from the endocardium or from the endothelial cells of the coronary vasculature, directly or through a decrease in LAP, or both, inhibits the release of ANF.[42] The results of experiment C and those from another study[33] give greater credence to intervention of exogenous NO in packaged forms.

Inhaled NO had a major effect on the kidney and a slight (on SAP and MAP) or no statistically apparent (on DAP and SVR) systemic effect. The kidney could be more sensitive to exogenous NO than the systemic circulation as demonstrated by the high sensitivity of RBF to NO synthase inhibition.[43] Indeed, the renovasculature showed significant modifications with low quantities of NO. Another hypothesis is that the kidney could more easily concentrate NO carriers or recuperate NO from its transport forms (local catabolism of *S*-nitroso compounds such as *S*-nitrosoglutathione, etc). The persistent diuresis after discontinuing PEHT and nitrergic treatments (stage IV) was in agreement with previous data.[32,33] It correlated with the persistent high pNO_x^- and uNO_x^- concentrations in experiment D or previous hypotheses such as intervention of other regulatory systems or a particular renal sensitivity to NO carriers for experiments C and E. It would imply that NO transported via GTN and that transported when NO is inhaled have similar (on the heart and kidney) and different (on the systemic circulation) effects. These could be explained by the nature of the implied packaged forms and their respective metabolism, particularly biotransformation of GTN to NO.

Metabolic effects

Because we deproteinized the plasma samples, NO (from iNO or released by GTN)-derived metabolites (NO_2^- and NO_3^-) and GTN-derived metabolites (1,3- and 1,2-glyceryl dinitrate, and glyceryl mononitrate) were potentially measured as pNO_x^-. At the end of stage III, infusion of ivGTN significantly increased arterial and venous pNO_x^- concentrations (table 3), and we observed only a statistical trend for iNO to increase pNO_x^- concentrations. This difference could be explained by a greater NO_x intake for ivGTN than for iNO and the larger number of metabolites of GTN. Other studies found significant differences in pNO_x^- concentrations between baseline and iNO treatment[7,19,20] with a longer period of inhalation and larger sample size.

During stage IV, pNO_x^- concentrations remained high in experiment D (ivGTN), but decreased in experiment E (iNO), whereas uNO_x^- concentrations remained high in all experiments. NO might be released during stage IV from its carrier proteins with diuretic and without vasoactive effect, and metabolized in NO_x^-. Moreover, GTN-derived metabolites could be present at the end of stage IV and measured as NO_x^-. The absence of haemodynamic effects of these compounds during stage IV could be explained by their low potency or the nitrate tolerance phenomenon. The explanation for the pNO_x^- decrease in experiment E is disruption of iNO administration.

In summary, previous studies have shown clearly a marked effect of iNO on pulmonary hypertension in pulmonary vasoconstriction models. Furthermore, in the passive PEHT model without pulmonary vasoconstriction, iNO maintained its pulmonary antihypertensive property. These results suggest that iNO may have direct cardiac effects. This study also demonstrated a marked effect of iNO on renal function, similar to that of ivGTN. We conclude that iNO had extra-pulmonary effects in an *in vivo* swine model and consequently that iNO cannot be considered as a pure selective agent on the pulmonary vasculature.

Reduction in nitrogen dioxide concentration by soda lime preparations during simulated nitric oxide inhalation

J. WEIMANN, J. U. HAGENAH AND J. MOTSCH

Summary

Nitrogen dioxide is formed during delivery of inhaled nitric oxide for the treatment of patients with pulmonary hypertension. Soda lime has been shown to absorb nitrogen dioxide. We tested three different commercially available soda lime preparations (Sodasorb, Drägersorb 800 and Sofnolime) for their efficacy in absorbing nitrogen dioxide and nitric oxide during simulated nitric oxide inhalation. All soda lime preparations absorbed nitrogen dioxide (15%, 24% and 34%, respectively). To test if this difference could be attributed to the potassium hydroxide (KOH) content of the different preparations, two other preparations with a higher (3.0% and 7.3%w/w, respectively) KOH content were tested and we found an increase in nitrogen dioxide removal up to 47% and 46%, respectively. We conclude that soda lime absorbed nitrogen dioxide during nitric oxide inhalation. This effect seemed to be moderate under simulated clinical conditions, but increased using soda lime with a higher KOH content. Nevertheless, we recommend continuous monitoring of inspired nitrogen dioxide concentration during clinical inhalation of nitric oxide. (*Br. J. Anaesth.* 1997; **79**: 641–644).

Key words
Gases non-anaesthetic, nitrogen dioxide. Pharmacology, nitric oxide. Equipment, scavenging devices.

Inhaled nitric oxide gas is a selective pulmonary vasodilator which has been used to treat persistent primary pulmonary hypertension of the newborn,[1] primary pulmonary hypertension,[2] ARDS,[3] and pulmonary hypertension in congenital heart diseases[4] and after cardiac surgery.[5] Potential side effects of this therapy include methaemoglobinaemia and formation of toxic nitrogen dioxide.

Nitric oxide is oxidized rapidly to nitrogen dioxide in the presence of oxygen. The amount of nitrogen dioxide formed depends on the concentration of nitric oxide and oxygen in the gas mixture, and the time available for the reaction. We have demonstrated previously that the amount of nitrogen dioxide formed during nitric oxide inhalation correlated with the inspired nitric oxide concentration, the fraction of inspired oxygen and the minute volume delivered by the ventilator.[6] Nitrogen dioxide concentrations up to 2.0 parts per million (ppm) were encountered.

It has been recommended as a safety standard that nitrogen dioxide concentrations should be monitored during inhalation of nitric oxide,[7 8] but a maximum tolerable concentration of nitrogen dioxide during clinical administration of inhaled nitric oxide has not yet been defined. The Centers for Disease Control recommend an upper limit of 5 ppm of nitrogen dioxide for occupational health.[9] However, inhalation of lower nitrogen dioxide concentrations has been demonstrated to increase airway resistance,[10] reduce mucocilliary activity[11] and impair host defence[12] in humans. Animal studies showed morphological changes such as loss of cilia, hypertrophy and hyperplasia of the bronchial epithelium, thickening and fibrosis of alveolar septa, and emphysema after long-term exposure.[13–15] Studies on the pulmonary effects of nitrogen dioxide in critically ill patients are not available.

In 1967 contamination of nitrous oxide cylinders with high concentrations of nitric oxide and nitrogen dioxide led to deleterious complications during general anaesthesia[16] and prompted a study by Kain which demonstrated for the first time the ability of soda lime to absorb nitrogen dioxide.[17] Recently, a few conflicting reports have been published showing complete,[18] marked[19] or no nitrogen dioxide absorption[20] by soda lime. Some of these studies were performed by passing a constant gas flow through soda lime cylinders,[18 20] while other authors tested soda lime with delivery systems used clinically.[19]

This study was designed to investigate the efficacy of three soda lime preparations in absorbing nitrogen dioxide and nitric oxide in a clinical setting. As the major difference in the chemical composition of these soda lime preparations is the potassium hydroxide (KOH) content, we also tested the hypothesis that nitrogen dioxide absorption could be increased by increasing the KOH content of soda lime.

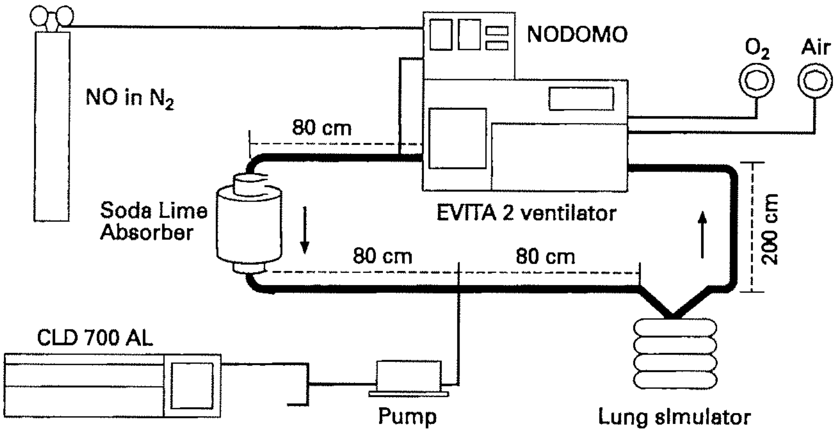

Figure 1 Scheme of the set-up, as can be used during clinical application of inhaled nitric oxide (NO). For detailed description, see text.

Methods

A mechanical lung simulator (Drägerwerk AG, Lübeck, Germany) was ventilated in a volume-controlled mode using an Evita 2 ventilator (Drägerwerk AG, Lübeck, Germany) at a constant rate of 12 bpm (fig. 1). A commercially available ventilator tubing set (polyethylene tubes with a diameter of 2.1 cm; B+P Beatmungsschläuche GmbH, Neunkirchen/Seescheid, Germany) was used in the inspiratory (length 240 cm) and expiratory (length 200 cm) limbs with a water trap in each limb connected via a Y-piece to the lung simulator.

Nitric oxide was delivered from a gas cylinder containing nitric oxide 1000 ppm in pure nitrogen (AGA, Lidingö, Sweden) into the inspiratory limb using a nitric oxide delivery device (NODOMO) (Drägerwerk AG, Lübeck, Germany). In order to maintain the nitric oxide concentration stable, the NODOMO adjusts nitric oxide flow proportionally to the flow of the ventilator.

We measured nitrogen dioxide and nitric oxide concentrations by chemiluminescence (CLD 700 AL, Zellweger-Eco-Systeme GmbH, Rösrath, Germany) in the inspiratory limb, 80 cm before the Y-connector. To prevent pressure-induced instability of the measurements caused by positive pressure ventilation, a pump was used to sample gas from the inspiratory limb. The gas sampling line of the CLD 700 AL was connected to a Y-piece at the outlet of the pump. Setting the suction rate of the pump higher than that of the CLD 700 AL ensures pressure-constant gas sampling by the CLD 700 AL. Calibration was performed after every 8 h of measurement with a gas mixture containing nitric oxide 30 ppm and nitrogen dioxide 7 ppm in pure nitrogen (AGA, Lidingö, Sweden).

An acrylic soda lime cylinder (Drägerwerk AG, Lübeck, Germany) with a diameter of 9 cm and a height of 12 cm (764 ml) was introduced into the inspiratory limb 80 cm beyond the ventilator.

To achieve different nitrogen dioxide concentrations, we changed settings for minute ventilation ($\dot{V}_E$) (5, 10 litre min^{-1}), fraction of inspired oxygen (F_{IO_2}) (0.25, 0.75, 0.99) and nitric oxide concentration (20, 40, 80 ppm). Measurements were obtained with (+SL) and without (−SL) soda lime leading to a single data pair for each setting.

Table 1 Chemical composition of the soda lime preparations tested

	Hydroxide content (% w/w)		
Soda lime	Calcium	Sodium	Potassium
Sodasorb	48.0	1.9	1.7
Dragersorb 800	45.0	2.1	2.0
Sofnolime	46.0	2.6	0.01
Special-1	44.0	3.0	3.0
Special-2	44.0	3.0	7.3

SODA LIME PREPARATIONS

We evaluated three different commercially available soda lime preparations for their ability to reduce nitrogen dioxide and nitric oxide concentrations: Sodasorb (WR Grace Co., Lexington, USA), Drägersorb 800 (Drägerwerk AG, Lübeck, Germany) and Sofnolime (Molecular Products Ltd, Thaxted, Essex, UK). Additionally, two soda lime preparations with a higher concentration of KOH were tested: Special-1 and Special-2 (Molecular Products Ltd, Thaxted, Essex, UK).

The soda lime preparations did not differ in colour indicator (ethyl violet) or granule size (4.0–8.0 mm in diameter). The chemical composition of the soda limes is given in table 1.

DATA ANALYSIS

Paired values were plotted in a scatterplot (values without soda lime (−SL) on the *X*-axis and corresponding values with soda lime (+SL) on the Y-axis). Linear regression was performed leading to the standard equation $y=mx+b$ of the fitted straight line. The difference between unity and the slope (m) of this line represents the efficiency of nitrogen dioxide or nitric oxide removal by the particular soda lime. r^2 values were calculated to test the strength of the linear correlation.

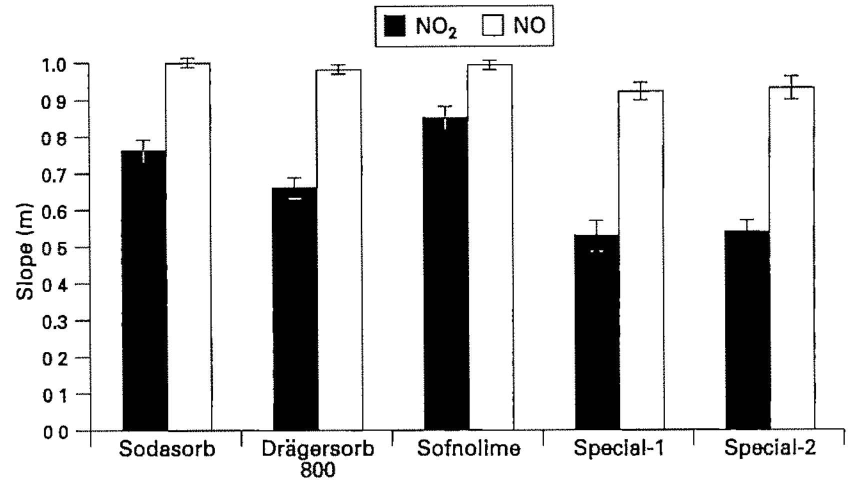

Figure 2 Reduction of nitrogen dioxide (NO_2) and nitric oxide (NO) concentrations expressed as slope values (SD of fitted lines) for the five soda lime preparations. Lower slope values indicate greater NO_2 or NO absorption.

Results

During administration of inhaled nitric oxide up to 80 ppm, nitrogen dioxide concentrations of up to 2.0 ppm were measured. The amount of nitrogen dioxide formed depended on the ventilatory setting: the higher the concentrations of inhaled nitric oxide and F_{IO_2}, and the lower the minute ventilation, the higher were the measured nitrogen dioxide concentrations.

Values of nitrogen dioxide and nitric oxide concentrations with and without soda lime showed a strong linear correlation, as indicated by r^2 values always exceeding 0.9.

All soda lime preparations reduced nitrogen dioxide concentration. Nitrogen dioxide absorption ranged from 15% (Sofnolime) to 34% (Drägersorb 800) for the commercially available soda limes and was higher for Special-1 (47%) and Special-2 (46%) (fig. 2).

While Sodasorb did not absorb nitric oxide, we found a slight reduction in nitric oxide concentration with Drägersorb 800 (2%), Sofnolime (3%), Special-1 (8%) and Special-2 (7%), respectively (fig. 2).

Discussion

We have demonstrated that three soda lime preparations (Sodasorb, Drägersorb 800 and Sofnolime) absorbed nitrogen dioxide formed during simulated ventilation with nitric oxide. Nitrogen dioxide absorption varied from 15% to 34% while nitric oxide absorption was 0–2%.

In contrast with our study, Stenqvist, Kjelltoft and Lundin[19] demonstrated a reduction in nitrogen dioxide concentrations in the inspiratory limb of their nitric oxide ventilatory system by almost 80%, but a different soda lime preparation (Q-sorb) and a larger soda lime cylinder (900 ml) were used. Ishibe and colleagues[18] showed complete absorption of nitrogen dioxide and 25% (Soda sorb) and 29% (Wako lime-A) absorption of nitric oxide using two types of soda lime. The high absorptions in the study of Ishibe and colleagues[18] may be explained by the long contact time between the gas mixtures and soda lime, resulting from a low and constant flow (1 litre min^{-1}) through the soda lime column (145 ml). Using a constant gas flow of 10 litre min^{-1}, which is more likely to represent clinical conditions, Pickett and colleagues[20] tested three different soda lime preparations. They found a marked reduction in nitrogen dioxide concentrations (80.6% and 83.9%) and a lesser reduction in nitric oxide concentrations (13.3% and 12.7%) by two types of soda lime. With a third type, both nitrogen dioxide and nitric oxide were absorbed completely as a result of an oxidizing indicator (potassium permanganate). Indicators used in commercially available soda lime preparations have no oxidizing properties. Therefore, the size of the soda lime cylinder, type (constant *vs* intermittent) and rate of gas flow through the cylinder, and chemical properties of the indicator may determine the amount of absorption of nitrogen dioxide and nitric oxide.

As the only difference between the three commercially available soda lime preparations was the concentration of potassium hydroxide (KOH), we hypothesized that the difference in nitrogen dioxide absorption may be related to the concentration of KOH. Therefore, we tested two soda lime preparations with an increased KOH content (Special-1 and Special-2). We found that nitrogen dioxide absorption increased to 47% and 46%, respectively. Nitric oxide removal was increased to a maximum of 8% (Special-2). Extending the reactions suggested by Kain[17] and Ishibe and colleagues,[18] the following chemical reactions during absorption of nitrogen dioxide and nitric oxide by soda lime may occur:

$$\begin{gathered}4NO+4NO_2+4NaOH+2Ca(OH)_2+4KOH\rightarrow\\2NaNO_2+2NaNO_3+Ca(NO_2)_2+Ca(NO_3)_2+2KNO_2+2KNO_3+4H_2O\end{gathered}$$

It is known that the radii of the hydroxides of group I elements decrease when the radius of the ion itself increases. This may account for the higher reactivity of the larger ions. As the sodium ion is smaller than the potassium ion, KOH may be more potent in binding nitric oxide or nitrogen dioxide. However, the exact mechanism by which KOH improves nitrogen dioxide absorption remains to be elucidated.

Increasing the KOH content of soda lime may be limited by the known effect of "caking", especially when humidifiers are used.[21] How the use of humidifiers may affect nitrogen dioxide and nitric oxide absorption by soda lime is not known. In one pilot experiment (unpublished data) we measured an increase in formation of nitrogen dioxide by approximately 30% when a humidifier was introduced into the inspiratory limp. Absorption of nitrogen dioxide and nitric oxide using Drägersorb 800 did not seem to be affected when measured over 10 min.

Other materials such as molecular sieve 5A[22] and charcoal[23] have been evaluated for their ability to reduce nitrogen dioxide and nitric oxide concentrations, but they lack specificity for nitrogen dioxide. While occupational exposure to nitric oxide and nitrogen dioxide in intensive care units has been shown to be low,[24 25] these and other non-selective scavengers of nitric oxide and higher nitrogen oxides were recommended to avoid environmental pollution during nitric oxide inhalation.[23 24 26]

As the dust from soda lime-containing hydroxide salts is irritating to skin and mucous membranes, appropriate handling of soda lime absorbers, as in anaesthesia systems, is essential.

We conclude that commercially available soda lime absorbed nitrogen dioxide formed during inhalation of nitric oxide. Although an increase in KOH content increased nitrogen dioxide removal, complete elimination of nitrogen dioxide from the inspired gas mixture could not be achieved. Therefore, soda lime may be helpful in preventing delivery of high nitrogen dioxide concentrations under specific clinical conditions, but continuous monitoring of inspired nitrogen dioxide concentration remains mandatory when nitric oxide inhalation is required.

REVIEW ARTICLE

Catalogue of human error

F. ARNSTEIN

"A life spent in making mistakes is not only more honourable but more useful than a life spent doing nothing." George Bernard Shaw. *The Doctor's Dilemma*, 1913.

err. to wander, go astray, miss the mark, make a mistake, to sin.[27]

To err is human. New skills are acquired and the existing improved by practise but intrinsic to all endeavour is the prevalence of error.

For discrete work-related tasks, workers average one error in every 1000 to 10 000 acts. This apparent low prevalence is misleading because many jobs average 20 000 acts per day and some approach 100 000.[62] Examining the performance of first and second year anaesthetic trainees during simulation, De Ande and Gaba found an incidence of 6.9 unplanned incidents per case, of which 27% were considered critical.[22] Currently, most errors recognized in anaesthetic practice are discussed locally. Wider debate may be provoked by the publication of case reports and articles, and in the courts. These processes are retrospective and inherently prone to misinterpretation. This article reviews human error terminology and examines some of the factors which influence the prevalence of error. It will be suggested that all of us make errors and are susceptible to misinterpreting information. The aviation industry has long recognized this and experience gained by that industry will be outlined, suggesting methods which may be usefully adapted to anaesthetic practice. To accept error as normal is a prerequisite to establishing systems to manage the risks. To study error is to not to apportion blame but to ask why. Understanding causality enables prevention.

Errors may be classified into two major categories: active and latent.[53] Active errors are events which occur immediately before an incident or accident. Latent errors are systems containing unrecognized faults which become evident under specific circumstances.

Active errors

Active errors can be subdivided into contextual, modal or psychological.

Mistaking a 1-ml ampoule of adrenaline for atropine is a contextual error in that the mistake occurs during a particular activity. However, such a description inhibits comparison between different activities. Modal descriptions are context free and may be subdivided into errors of omission, repetition, substitution and insertion (commission), and allow easier comparisons. Such descriptors are broad so that focus may be lost and there is no attempt to describe error causation, making prevention strategies difficult to formulate. Psychological definitions aim to define cognitive mechanisms that lead to error and should make error causation predictable and comparable. Errors described in this manner have been divided into slips (action not intended) or mistakes (poor or faulty planning). Usefully, errors may be classed as knowledge, skill, or rule based, with some observers describing an additional group of technical errors.

KNOWLEDGE BASED ERRORS

Knowledge based errors originate in a background of inadequate knowledge or experience. Experience is important because it enables the deployment of a generic solution to a novel situation. However, examining the role of experience on the response to simulated critical incidents, DeAnda and Gaba suggest that experienced staff are as likely as trainees to make errors (67.5% human error compared with 72.2% and 56.6% for first and second year anaesthetic residents, respectively).[21]

RULE BASED ERRORS

Rule based errors occur when there is a failure to apply a rule or an inappropriate rule is used, for example performing cardiopulmonary resuscitation when the electrodes of the electrocardiogram have become detached. Anaesthetic seniority may confer an increased risk of making errors of this type as more short cuts are used. Such deviations are also termed violations or intentional errors.

Key words
Anaesthesia, human error. Anaesthesia, aviation. Anaesthetist, human error.

FRANCIS ARNSTEIN, MB, CHB, FRCA, DAVMED, Department of Anaesthesia, Edinburgh Royal Infirmary NHS Trust, Lauriston Place, Edinburgh EH3 9YW.

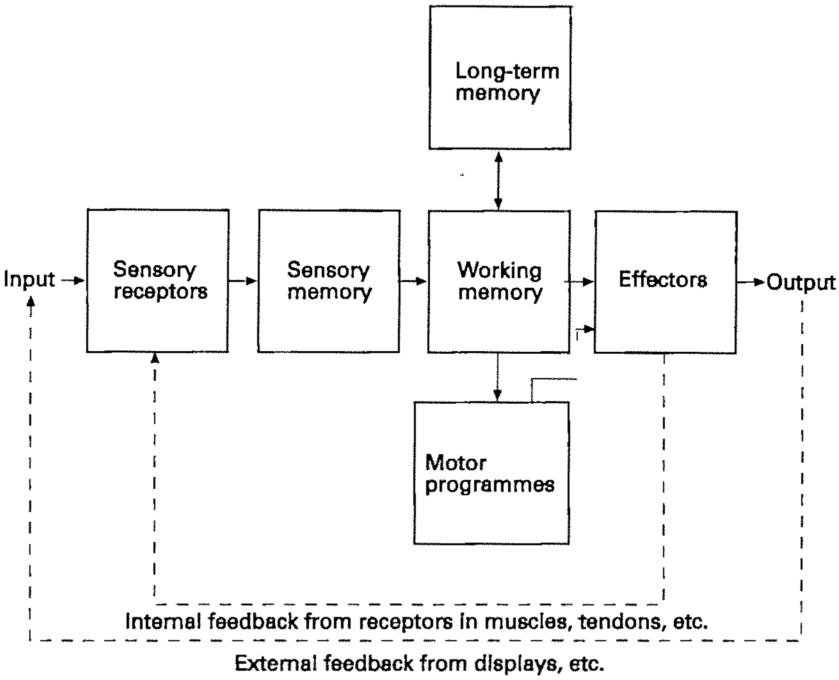

Figure 1 A model of human information processing (reproduced with kind permission of Butterworths, London).

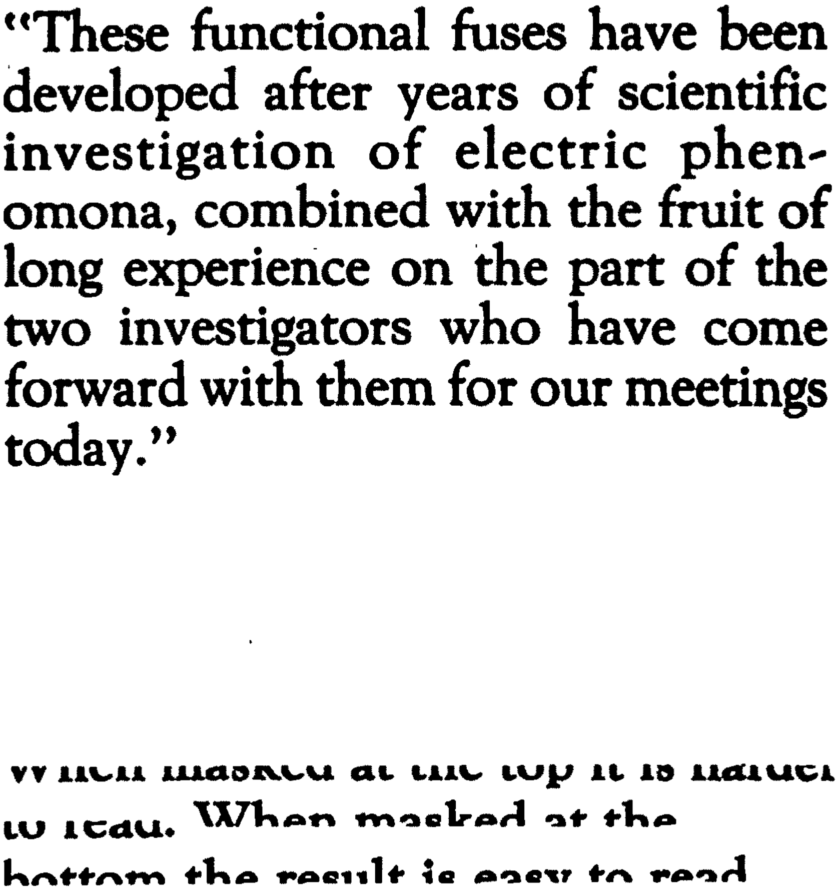
SKILL BASED ERRORS

Skill based errors which incorporate slips and lapses relate to errors in conscious and subconscious (automatic) cognition. Human information processing may be described by the model developed by Rasmussen (fig. 1). The mind may be viewed as an information processor provided by a series of filtering sensors and memory systems enabling comprehension of a data set without conscious recognition



"These functional fuses have been developed after years of scientific investigation of electric phenomona, combined with the fruit of long experience on the part of the two investigators who have come forward with them for our meetings today."

When masked at the top it is harder to read. When masked at the bottom the result is easy to read

Figure 2 Reduncancy in writing. How many times does the letter "f" appear in the top paragraph? (reproduced with kind permission of Robson Books, London).

of the whole. For example, the written word contains much redundancy both in content and form (fig. 2).[7]

Subconscious or motor programmes enable many tasks to be performed simultaneously and rapidly, freeing cognitive power for conscious effort. Although motor programmes are fast and efficient they are also rigid and occur by definition without awareness. Therefore, it is possible (and in daily life is common) to select the wrong motor programmes for the task or develop a programme with an in-built fault. Even conscious activity requires a balance between speed and accuracy but during emergencies the time available to perform a task is often limited.

TECHNICAL ERRORS

Technical errors are described in the anaesthetic literature but originate strictly from outside the individual. For example a "failed" extradural may result from performing the procedure correctly on a patient with atypical anatomy.

Within these broad categories, sub-classifications have evolved. Norman has described five types of slip.[48]

Capture errors: fault caused by the use of an inappropriate motor programme, for example giving a neuromuscular blocking agent to a patient with a known difficult airway.

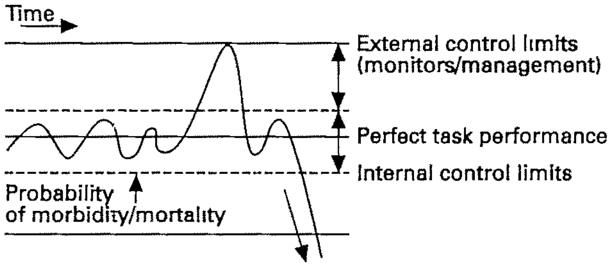
Description errors: using the correct action on the incorrect object, for example turning off the oxygen instead of the nitrous oxide. Selecting the wrong ampoule has been described as a description error or simply absentmindedness. "Absentmindedness" may be interpreted by the layman as implying carelessness and fails to recognize that such errors are intrinsically normal.

Memory errors: omitting elements of an intended action sequence.

Sequence errors: performing task elements in the wrong sequence.

Mode errors: correct action used for equipment currently in the wrong mode, for example turning off the ventilator when the breathing system is in ventilation mode.

Additionally, three further forms of error are described as *fixation errors*: despite evidence to the contrary, continuing with an inappropriate plan, dealing with everything except the real problem and believing the evidence is falsely positive.[32] These may be seen as "cognitive tunnel vision".



Time
External control limits (monitors/management)
Perfect task performance
Internal control limits
Probability of morbidity/mortality

Figure 3 The error train: an incident/accident model.

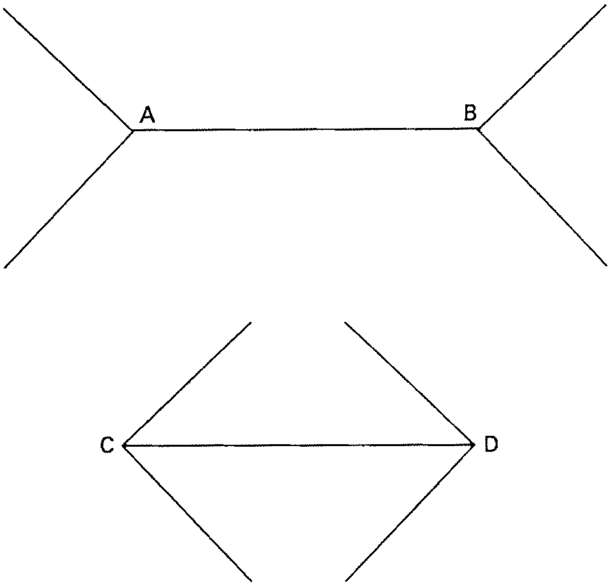


Figure 4 The power of simple illusions. The Muller–Lyer illusion. Does AB=CD? (reproduced with kind permission of Robson Books, London).

Monitoring and control systems should be in place to advise the anaesthetist that he or she is failing. These should not impinge continuously on his conscious effort. To do so may interfere with cognitive function and induce irritation. Davies described a useful incident/accident model ("Human error—prevention and investigation". Lecture given to the Royal College of Anaesthetists Anniversary Forum on *Risk Management for Anaesthetists*, 1995). This may be seen as an error train (fig. 3). Remaining on the correct and most direct track requires good internal control and when this fails, timely and accurate intervention by external monitors. Failure of both may lead to an incident or accident. The associated morbidity corresponds to the degree of deviation.

Human information processing systems may be unable to detect errors of recognition (illusions),

imagine external stimuli (hallucinations) or may make false cognitive hypotheses (delusions). Simple illusions may be powerful (fig. 4). Prolonged exposure to one set of stimuli may affect the perception of subsequent information. Some illusions are so powerful that they are impossible to resolve leaving the observer bemused but conscious of his fallibility (fig. 5).

Failing to maintain accurate contact with reality may lead to disorientation. In aviation, two forms of disorientation incidents are recognized.[5] Type I is defined as when the pilot fails to recognize that his perception is incorrect whereas during a type II incident he senses that the cues presented to him may be inducing a false perception (fig. 6). The former represents a greater hazard in that an erroneous situation exists but the pilot remains unaware and this is supported by aviation accident mortality data. It would seem reasonable to extrapolate these modes of disorientation to other human activities, including the practice of anaesthesia.

External monitoring systems may assist in resolving the cognitive conflict but the disorientation may be so powerful that alarms are considered to be faulty and are ignored. In aviation it is recognized that it is best to avoid the circumstances which may be disorientating. Therefore, training emphasizes the early recognition of risk situations with the deployment of well rehearsed procedures to optimize the chance of maintaining accurate contact with reality. In a similar manner the use of algorithms during anaesthesia assists; 62% of anaesthetic difficulties can be resolved within 60 s by reference to basic ABCD management.[54] The use of simulation should prepare anaesthetists for rare adverse events.[33] However, it is recognized that memory deterioration demands that refresher courses should be offered at regular intervals and probably not exceeding 6–12 months.[46 60] Unfortunately, during crisis management there may not be enough time for logical analysis and printed *aide-mémoires* can be invaluable while advances in computer technology is enabling the introduction of rapid access databases.

Latent errors

Latent errors are inadequacies or failures of ergonomics or training, incorrect policies or protocols, inadequate assistance or supervision, social and cultural factors, including language, the physiological state of the patient and chance. Chance is analogous to fate, being defined as risks which have such low probabilities that estimates cannot be assigned. An example might be injury caused by metal fatigue in an operating table where such an event could not be foreseen during the design of the table or even after extensive use.

The risk associated with a latent error must be viewed with caution because to occur may require shaping or enabling factors. For example an anaesthetic monitor may cause no difficulty when used in optimal lighting conditions but the presence of screen reflections or an anaesthetist with defective colour vision[25] may degrade the information it provides so that it fails to warn and may contribute to increased stress and wasted cognitive effort.

Examples of latent errors reveal the multitude of potential problems which may act singly or in combination to induce error. Equipment may be designed by those who will not use it. The development of anaesthetic monitors has been rapid but they are rarely integrated, and they often have many alarms of similar form but representing widely differing pathophysiological states; that is cues lack specificity. Displays may be too small, use inappropriate colours and have warning messages that appear on the periphery of the screen (fig. 7). Poor integration inhibits the flow of information to the observer who must make frequent body or head movements or use saccadic vision. Audible alarms may have similar tones, and without adequate separation in loudness between alarms and background noise may be inaudible.

Inappropriate default alarm settings may prevent the monitor from warning as may failure to set the alarms. Variations in equipment and lack of training in its use increase the likelihood of error and alter the

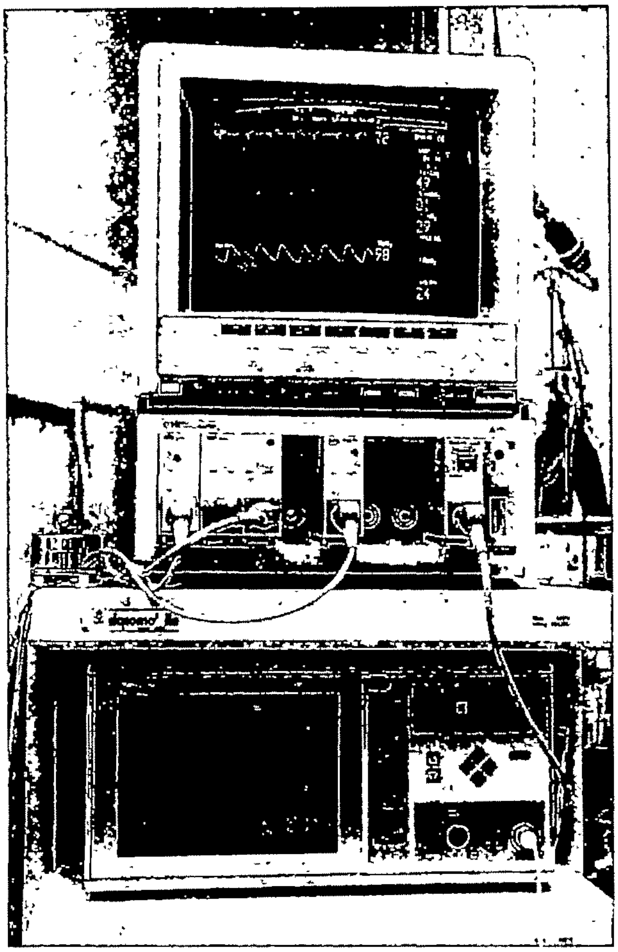

Figure 7 Ergonomic design failures in an anaesthetic monitoring system. "Alarms suspended" shown at the screen periphery (upper monitor) or shown as remainder of screen information (lower monitor)

perceived stress. Special circumstances, for example neurosurgery or MRI scanning, may prevent direct anaesthetist–patient contact, increasing dependence on monitors. An aviation analogy would be transferring from visual to instrument flight rules during poor weather or night flying, a situation recognized to increase accident rates, stress and workload.

Even simple items of anaesthetic equipment may contain the properties of a latent error, for example the packaging of disposable items such as the Guedel oropharyngeal airway using materials which may occlude the airway (fig. 8). Drug ampoule labelling has been the attention of much debate and a comprehensive solution to the misinterpretation of ampoules has yet to be found.[19 26 49 50]

Figure 8 A latent error in the packaging of a Guedel airway.

Frequently latent errors cannot be identified before an activity and only vigilance and luck prevents more incidents becoming accidents. Case reports, safety notices and the roles of the Committee of Safety in Medicines and Medicines Control Agency are examples of systems which involve vigilance but also demand dissemination of important information accurately, expediently and with clarity.

PSYCHO-PHYSIOLOGICAL STATUS

The psycho-physiological state of the anaesthetist may influence considerably the incidence of error and his or her performance. Factors to consider include the effects of immediate and underlying stress and personality trait. Eyesenck described three descriptors of personality type: extroversion (extroversion and introversion), neuroticism (stability) and psychotism. Extroversion and neuroticism have been identified as useful indicators of risk personalities in aviation and road traffic accidents but although personality tests are used by civil airlines, their use by the military is limited. Good pilots and perhaps good anaesthetists tend to be stable extroverts. Extroverts who are unstable make errors but of a different nature to introverts, tending to be risk takers enjoying the thrill of being near the edge. In contrast the unstable introvert gives in early when difficulties are mounting. In military aviation the latter may eject early with the unnecessary loss of the aircraft while the former does not eject at all with the loss of aircraft and pilot. Simple observation may identify anaesthetists who tend to fall into one category or another with associated risk taking and error prone behaviour.

Personality

The influence of personality must be viewed in the light of the presence of extraneous stressors. Although stress is usually viewed as a negative phenomenon this only describes those situations which are outside normality and necessity. In 1908 Yerkes and Dodson described a model of the

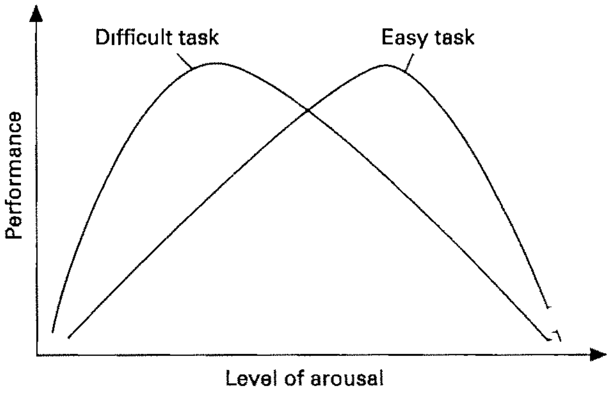

Figure 9 The Yerkes–Dodson relationship between arousal and performance (reproduced with kind permission of Butterworths, London).

influence of stressors on performance demonstrating that the optimum performance of a task occurs at a particular stress level (fig. 9).[69] Too little leads to drowsiness, reduced vigilance, errors of omission and slowed reactions. Too much results in increased response to false alarms, narrowing of attention, disruption of organized thought, startle reactions, increased speed but reduced accuracy of motor activity, and finally panic. Others support the view that excess workload results in a reduced capacity for information processing.[41] However, the Yerkes–Dodson concept can be criticized.[29] For example it suggests that an identical performance decrement will occur at high and low stress levels whereas it is recognized that these states produce opposite effects on attentional selectivity. Further, performance changes caused by heat-induced arousal are different from those caused by noise. Despite these reservations the inverted "U" relationship between arousal and performance represents a useful model.

Stress factors

Stressors appear in many forms. They may be immediate in time and place such as noise, heat, vibration and excess or too little light, or they may be more remote but no less intrusive: family and financial worries, career uncertainty, effects of unusual or excessive work schedules, poor team co-operation and the memory of prior incidents or accidents. Inadequate debriefing and support after the latter may induce a vicious cycle of increased endogenous stress and risk of accident recurrence. Stress, intrinsic to the task, may arise acutely if the task is not completed successfully. Consequently the performance of the individual may deteriorate inducing a vicious cycle of more stress and less success (synonymous with the headless chicken).

The effect of different extraneous stressors on performance has been subject to much study. Anaesthesia is often practised in noisy environments and the effects of noise have been reviewed by Kam, Kam and Thompson.[40] The perception of sound is complex and several different scales have been derived to describe sound levels, human sound perception and noise.

Aural communication between the anaesthetist and his colleagues and monitors requires an acceptable signal to noise ratio. For all the elements of speech to be heard they must be spoken at least 15 dB above the ambient noise level. However, there is much sound redundancy in speech and intelligibility depends on the content, context and prior experience of the listener. Consequently, a 10-dB separation usually allows 100% reception. Sound levels exceeding 105 dB cause discomfort, and intelligibility may fall because of sound distortion by the ear itself. Auditory alarms may be subject to auditory masking. For a second alarm to be recognized the volume required increases as the sound frequencies of the two alarms approach each other.[52]

Abrupt changes in noise level may induce startle reactions reducing performance long after the sound and is the mechanism of action of the military stun grenade. High continuous noise levels increase arousal, reducing error in repetitive, monotonous tasks. However, performance of complex tasks decreases with reduced accuracy, poor response to the unexpected, increased annoyance and induction of fatigue. Additionally the effect of noise cannot be viewed in isolation to other stressors nor can the accuracy of hearing be isolated from the performance of other faculties.

Table 1 Effects of vibration on speech, sight and motor function

Function	Organ or tissue resonant frequencies (Hz)	Effect
Speech	6–20	Loudness modulation with ↓ intelligibility
Vision	20	Intraocular structures vibrate. Facial flutter
	30–40	Vestibulo-ocular reflex: compensation with
	70	↑ effort to 25 Hz.
		Pursuit reflex: ↓ function >1 Hz or 40° s^{-1}
Motor	2–6	↓ control outstretched hands

Vibration is a stressor not commonly experienced by anaesthetists but can be of significance to those involved in patient transport, particularly in helicopters. Different structures of the human body have varying natural resonances, and exposure to vibration may impede sensory input and motor function (table 1). Helicopter flight may induce a disparity between the oscillation of the eye and the display of the monitor and intense effort may be needed in trying to obtain useful visual information. Additionally vibration may cause significant changes in arterial pressure, reduce tactile feedback, induce fatigue and motion sickness. MacNab and colleagues measured noise and vibration in emergency transport vehicles used for the transport of neonates (land, air and water) and recorded maximum vibration levels in excess of those considered extremely uncomfortable for adults.[46]

The effects of fatigue on performance and error have been assessed. Fatigue is linked to circadian influences and work schedules. Perhaps surprisingly studies have failed to show conclusively that fatigue is associated with a significant degradation in performance but some have suggested increased response times and reduced accuracy. An analysis of adverse occurrences in an intensive care unit demonstrated peak reporting between midnight and 01:00.[1] Clearly, results depend on the level of fatigue which is influenced by the time of day, time since sleep or rest, time on task and nature of task. In addition, although fatigue may not induce failure it may reduce feelings of well-being.

In 1967 Holmes and Rahe evaluated and scored life stressors in terms of life change units.[38] The development of the "schedule of recent experiences" enabled 42 life stressors to be weighted according to subjective assessments. There is a correlation between this score and the prevalence of physical and psychiatric illness. This scoring system has been criticized, particularly in its failure to separate "positive" experiences from "negative" and a further development by Sarason, Johnson and Siegel suggests that negative events are of much greater importance than change alone.[57] Life stress has been demonstrated to be present in those blamed for aviation accidents but absent from those considered blameless.[3]

Excess or adverse stress may induce failure to cope. This may result in internalization of feelings leading to social withdrawal and depression. Conversely, externalization may be suspected by increased defensiveness, hostility, arrogance, projecting blame onto others ("acting out") and risk taking. General behavioural and life style changes may develop with increased alcohol ingestion, drug misuse, fatigue and illness.

Vigilance by colleagues and managers may help identify those who are failing to cope with stress. The aviation world accepts that this is not a medical disorder in itself and has replaced the term "failing aviator syndrome" with "aviator at risk".[47] Most stress reactions are now viewed as a normal response to excess stress and are termed "adult situational reactions" with the emphasis on the transitory nature of the stressor. It is increasingly accepted that anyone could have such an experience.

A greater understanding of the effects of stress may produce an increased awareness that stress is normal, occurs in everyone's lives and is usually transitory. However, circumstances may dictate that help is needed and the systems used by the aviation industry result in a high recovery rate. To encourage discussion, it is imperative that a request for help is not construed as an admission of failure. It is important that those who assist are appropriately trained and empathetic. Education in human factors is taking a more prominent position in the aviator's curriculum and perhaps should be considered formally in anaesthetic training. There are systems for helping the "anaesthetist at risk" such as the national sick doctors scheme and at a local level the allocation of individual mentors. The publication of articles in the anaesthetic literature discussing stress in the profession demonstrates an increasing awareness and has been recognized by the Association of Anaesthetists of Great Britain and Ireland with the introduction in November 1992 of stress management courses.[24 59] These have always been over subscribed with greater interest expressed by consultants than trainees (personal communication). To admit that there is a problem is the first step to finding solutions.

I Illness?

M Medication?

S Stress?

A Alcohol?

F Fatigue?

E Eating?

Figure 10 Retaining own responsibility for current competency by checking one is not adversely affected by any of the above.

The individual can usefully retain much responsibility for assessing his or her current stress level and make a judgement as to current competency. Aviators are encouraged to use "IMSAFE" (fig.10) before each flight and this approach is readily transferable to anaesthetic practice. Reductions in trainee hours of work and increased supervision should reduce some of the elements shown.

Training and motivation may have significant effects on an individual's performance, enabling optimal results to be achieved within the constraints of personality, aptitude and cognitive resources. The Royal Air Force assesses the aptitude of potential aircrew recruits with a combination of psychometric testing (the p tests), leadership tasks and formal interviews. Specific tests such as the defence mechanism test correlate well with performance during military training and service.[37] Currently, recruitment into anaesthesia tends to be based on a short interview and the provision of written references. With the implementation of the Calman report and introduction of "career" training, more careful candidate assessment may be appropriate. The study of training and motivation forms part of the remit of psychologists working in education and industry. Clearly both have important implications on the prevalence of error.

Team effort

So far the emphasis has been on the individual and the man–machine interface. However, it is recognized that the anaesthetist represents just one part of a complex system. The Australian incident monitoring study demonstrated that the system directly contributed to 25% of problems and was implicated in 90%.[55]

Individuals may be expected to use guidelines and procedures which have been developed by others, often working as committees. The work of a committee might reasonably be expected to reach an average or measured response to a problem. However, this is not always so. "Risky shift" represents the effect of the group's solidarity in promoting a view which would otherwise be considered too extreme by any one individual. "Group think", a concept developed by Janis, is a phenomenon associated with very cohesive groups where individuals act, albeit subconsciously, to preserve the integrity of the group rather than express dissent. Consequently sensitive issues may be ignored. Importantly the committee's conclusions may be based on deliberations far removed from the situation under discussion.

Pilots work as members of a team which includes other aircrew and ground staff. Anaesthetist's work similarly requires a co-ordinated effort with other theatre staff and anaesthetic colleagues. Sharing workload within a team has advantages and disadvantages. The benefits include the allocation of task elements to individuals with specific expertise and may enable the workload for any one person to be kept to an acceptable level. However, the successful division of labour requires good leadership, communication and co-ordination. The current approach to the early management of trauma demands a well practised and cohesive specialist team. To achieve this requires time and training. Without this investment personality differences, lack of common language and intention are likely to increase the probability of error with a suboptimal outcome. In contrast with the parallel design of the trauma team, traditional management structures have tended to be of a serial format. Although the latter may emphasize the hierarchical nature of responsibility, the longer lines of communication may reduce management's awareness of the requirements of those in direct contact with patients.

Accidents may reflect the quality of senior management, a point emphasized in the official reports on the Piper Alpha explosion, the Kings Cross underground fire and Clapham Junction railway accident.[43]

The need for formal training in team management was recognized in the civil aviation industry with the introduction of line orientated flight training (LOFT) by North West Airlines in the 1970s and since then cockpit or crew resource management courses (CRM) have become an integral part of commercial civil flying training. Foushee described several examples where failure of communication within the team and poor assignment of responsibilities led to an in-flight critical incident or accident (address to the Western Psychological Association, San Francisco 28 April, 1983). Within the industry it is recognized that developments in aviation technology present new challenges to aircrews and therefore CRM training must be adapted accordingly.[14] Perhaps surprisingly the Royal Air Force does not yet recognize this need believing that the attributes are identified during the initial pilot selection process and the acquisition of additional skills is an integral part of military aircrew training.[2] LOFT involves using a high fidelity simulator to expose all the flight crew to a complete "flight" during which a simulated emergency occurs, the nature of which requires good team co-ordination to achieve a successful outcome. The simulator also enables accidents and incidents to be reproduced providing useful information during accident investigation. The development of simulators by anaesthetists should enable a similar approach to evolve but until recently most work has focused on the performance of the individual rather than the whole theatre team.[42 158] Additionally, anaesthetic simulators are considered expensive and are not commonplace. The high cost of aviation simulators is offset by the recognition that many situations cannot be safely created in the air, rare scenarios need to be practised and the high fidelity makes simulated flight essentially "real" and therefore cost effective. Ovassapian has shown that the initial acquisition of fibreoptic intubation skills using simulation can be more efficient than training with patients.[51] Commercial aviation simulators are required to be licensed and it may be that the performance of anaesthetic simulators needs to be assessed formally if simulation is to become a routine part of training. In the medico–legal field, anaesthesia is considered to be a high-risk specialty. The growth in litigation may ensure that anaesthetic simulation becomes routine and cost effective.

The performance of the team depends significantly on the qualities of its leader. In the latter half of this century psychologists have focused much of their interest on the interaction between individuals and the psychology of leadership. In 1971 Fielder proposed two orthogonal leadership factors.[30] Successful leadership requires a balance between the dual requirements of achieving the task (initiating structure) and good group relationships (consideration). Best productivity is achieved by leaders who score highly for both goal (G) and people (P) orientation. In comparison, low G and high P scores produce good quality but poor productivity and high G and low P scores result in more work achieved but of poor quality.

It is important to remind ourselves that error does not equate with negligence. However, error is often deemed culpable in retrospect. Retrospective analysis is fraught with difficulties, not least because memory degrades rapidly tending to simplicity and coherence, contemporaneous records cannot fully and accurately reproduce the actual event and investigators's interpretation may be influenced by their own prejudices. The need to examine all the circumstances surrounding an error as they existed at the time is to be emphasized. This said, Caplan and colleagues demonstrated agreement between

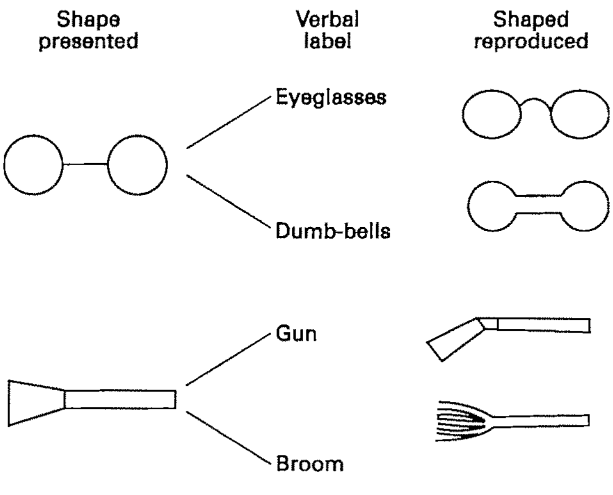

Figure 11 Effects of language on the reproduction of shapes (reproduced with kind permission of Butterworths, London).

anaesthetists of widely differing backgrounds when asked to review anaesthetic mishaps.[9] Memory may be influenced by many factors, for example auditory cues can distort visual or other memory significantly (fig. 11) and this failure is used to advantage by the legal profession.[10] Culpability may only be appropriate for situations where there was extreme departure from acceptable standard practice without any extenuating circumstances.

Identifying errors

Current systems used to identify error in anaesthetic practice are manifold (table 2). However, all have limitations, particularly in that they rarely aim to provide a complete answer to why an error occurs. Anonymous critical incident reporting has been introduced and large studies such as the Australian incident monitoring study have reached some comprehensive conclusions. In particular, it is recognized that 80% of critical incidents may have their origins in 20 categories.[65] The Royal College of Anaesthetists has published findings from its critical incident pilot study but although this categorizes the events it fails to focus on causation.[36] Focusing resources on a limited number of problems may be the most efficient method of reducing error. Critical incident reporting systems are often based on the use of questionnaires but it is recognized that these must be very carefully designed.[18 64] The use of closed questions may impose rigidity resulting in loss of valuable information whereas free expression may provide much data but no answers. The overall length and structure of the questionnaire is important if the responder is to be motivated to complete it. Careful wording of the questions is needed to minimize the problem of response sets (acquiescence: giving an answer as expected by the question; social desirability: answering as the expected norm). Semi-structured interviews have been used and may be more effective in capturing data.[16] Researchers in ergonomics have used many techniques for identifying human error: Kirwan compares 12.[42] This suggests that a universally applicable method has yet to be discovered.

Identification of an error prone situation may enable a detailed and prospective analysis of the problem to be undertaken. Several techniques have been developed which can be used to assess the workload associated with a particular flying task. The subjective workload assessment technique (SWAT) involves subjective examination of three core elements: time load, mental effort and psychological stress. These are scored by the crew at regular time intervals and then the whole task can be analysed to detect phases when workload is inappropriate and error becomes likely. Application of these techniques in anaesthetic practice may help identify periods of risk. However, such analyses are very labour intensive and the presence of an observer is likely to influence the behaviour of the observed.

The review of anaesthetic mishaps should be made by those trained in seeking the truth in a sympathetic and neutral manner. The keywords for investigators are accessibility, confidentiality and advocacy. However, occasions may demand that public safety assumes priority. Anaesthetists should be encouraged to record confidentially and anonymously their experiences as soon as possible after the event without endeavouring to analyse or justify their actions. Investigation of individual incidents should entail examination of contemporaneous records supplemented by questionnaires and interviews. The data should be pooled to provide a database from which patterns of error may emerge encouraging prevention.

The work of the anaesthetist exposes him or her to emotionally stressful situations. Involvement in cases where patients suffer unexpected injury or death can be particularly difficult to cope with, especially if the doctor considers him or herself to be at fault. Post-traumatic stress disorder (PTSD) is now a well recognized clinical disorder and was accepted into UK law after the Herald of Free Enterprise disaster. It is defined as "the development of characteristic symptoms in an individual after a psychological traumatic event that is generally outside the usual range of human experience and one that would be markedly distressing to anyone". It may last indefinitely. To minimize the development of PTSD, those involved in anaesthetic mishaps may need to undergo critical incident stress debriefing. After aviation accidents there are well established systems for helping all involved and guidelines have been published.[13]

Table 2 Current mechanisms for investigation of error, critical incidents and accidents in anaesthesia and aviation

Anaesthesia	Aviation
Discussion with colleagues	Discussion with colleagues/line manager
Discussion with senior mentor	Discussion with aviation medicine specialist
Morbidity and mortality conferences	Confidential human factors incident reporting programme
Critical incident studies/reports	Case reports and hazard notices published in journals
Medical audit	Civil Aviation Authority investigations
National mortality surveys (Scottish mortality study)	Coroner or fiscal enquiries
Employing authority enquiries	Air Accident Investigation Branch (Department of Transport)
Case reports and hazard notices published in journals	US National Transportation Safety board investigations
Coroner or fiscal enquiries	International Civil Aviation Organization reports
Confidential enquiry into peri-operative deaths	Media investigations
Medical Defence Organization reports	
General Medical Council deliberations	
Media investigations	

Table 3 Prevalence of human error in critical incidents in anaesthesia and aviation. (m)=Military aviation, (s)=anaesthetic simulation. *64% for instant reporting and 70% for retrospective analysis; †58% aircrew error/47% supervisory error, ‡hot-air ballooning

Anaesthetics (Reference)	Human error (%)	Aviation (Reference)	Human error (%)

Prevalence of human error

To justify expending resources to reduce the incidence of human error it is important to assess the size of the problem. Mortality directly contributable to anaesthesia is quoted at 1 per 10 000 anaesthetics given to approximately 3 per 500 000.[8, 20] Morbidity is harder to estimate and is probably under reported. The risk of death in an aircraft accident is of a similar order. In 1982 there were just over 1000 fatalities in passenger aircraft accidents out of a total of approximately 755 million passengers journeys over 14 million flying hours (approximately 1 death per 75 500 passengers).[39] It is difficult to estimate the incidence of critical incidents, particularly as definitions vary. Derrington lists 10 definitions from different studies.[23] I propose the following: "a critical incident is a human error or equipment failure that if not corrected leads to an undesirable outcome. An accident is the consequence of a critical incident, which uncorrected, progressed to an undesirable outcome".

It has been suggested that the word accident represents a conceptual ambiguity and should be disqualified from technical use.[28]

Despite differences in study design and definitions, estimates of the contribution of human error to critical incidents and accidents in anaesthesia and aviation during the past 15 yr are surprisingly similar (table 3). This supports the notion that there are fundamental mechanisms causing error. The prevalence has appeared to increase in both anaesthesia and aviation which may reflect growing complexity but may also be a result of increased recognition.

Improvements in equipment, training and regulation have failed to reduce the contribution of pilot error to aviation accidents. This may reflect the increasing complexity of the aviation world. The practice of anaesthesia has also become increasingly complex. Patients and their relatives have greater expectations as do our surgical and nursing colleagues. This is reflected by the growth in medical litigation. In the USA 80% of malpractice claims filed between 1935 and 1975 were filed during the last 5 yr of that period.[11]

For commercial pilots human factors education is incorporated into cockpit or crew resource management courses and both trainees and the qualified are taught how to recognize and manage stress. Anaesthetists may benefit from similar formal training with the potential for improved team effort, staff satisfaction and patient outcome.

Conclusions

In summary, although the practice of anaesthesia is commonly deemed safe, the profession rightly seeks for continual improvement in quality. Human error remains and will probably always be the primary cause of accidents. This error may be focused on the performance of the individual, the team or the system. Its origin is likely to be multifactorial and complex to resolve. Gaba and colleagues have proposed strategies for preventing anaesthesia accidents but there is a need to continue to research into the causes of error, both in the field of research psychology and specifically in the practice of anaesthesia.[15, 34] Error and critical incident terminology needs clarification so that comparative work becomes easier. There is also a need for anaesthetists to be formally trained in human factors, including team management. Finally, the appointment of an anaesthetic accident investigation team, working independently of any medico-legal process, could provide the necessary expertise to reach valid conclusions. To this end the establishment of the Critical Incident Pilot Study Steering Group by the Quality of Practice Committee of the Royal College is a useful step.

"The greatest mistake you can make in life is to be continually fearing you will make one."

SHORT COMMUNICATIONS

Pre-emptive analgesia using local anaesthesia: a study in bilaterally symmetrical surgery

W. I. CAMPBELL AND R. W. KENDRICK

Summary

Two studies were carried out in patients undergoing bilaterally symmetrical lower third molar surgery under general anaesthesia. In the first study observations were carried out in 40 patients, using McGill pain questionnaires and visual analogue scales (VAS), to assess the variation in pain intensity between the two sides in each individual on the morning after surgery. The within-patient variation in pain intensity indicated that a sample size exceeding 30 was required to show a difference of more than 10 mm on the VAS and achieve a power of 90% at the 5% level of significance. The second study was carried out to determine if local anaesthesia administered before rather than after tooth removal rendered any benefit. Each of the 38 patients acted as their own control; one side was allocated randomly to receive the local anaesthetic before operation and the other side after operation. The difference in pain between the pretreated and post-treated sides in each individual was assessed using a McGill pain questionnaire on the morning after surgery in addition to two VAS (one for each operation side) after operation, at 6 h, 1 and 6 days after surgery. There were no significant differences in pain at any time using any of the above methods. (*Br. J. Anaesth.* 1997; **79**: 657–659).

Key words

Analgesia, pre-emptive. Anaesthetics local. Pain, measurement. Pain, postoperative. Surgery, dental.

Recent findings indicate that tissue injury may generate prolonged excitability within the central nervous system (CNS) and that postoperative pain may be reduced by preventing CNS excitation during surgery. This hypothesis is based on animal work which showed that elimination of spinal cord bombardment by nociceptive transmissions prevented cord hyper-excitability.[1] Preliminary clinical research appeared to substantiate the advantage of pre-emptive analgesia,[2] but other studies were unable to confirm that there was any benefit from preoperative administration of analgesia compared with postoperative administration.[3]

Most studies in acute pain illustrate large inter-patient variation in the rating of pain intensity. Many factors such as sex, age, race, anxiety and pain tolerance may alter the level of perceived pain.[4 5] In an attempt to reduce these confounding variables to a minimum, this study was designed so that patients would act as their own control. The aims of the study were to quantify the difference in pain intensity between two sides of the body when bilaterally identical surgery was carried out and thus determine a sample size for further studies of this type, and to determine if preoperative administration of local anaesthetic rendered any advantages compared with postoperative administration.

Methods and results

This two part study was granted approval by the Ethics Committee of the Queen's University of Belfast. We studied 40 ASA I and II patients undergoing removal of both lower third molar teeth, provided that the teeth were bilaterally symmetrical on radiological examination. If upper third molars were also to be removed, patients were included only if all four third molars were removed. Informed verbal consent was obtained in each case. Before surgery, patients were shown how to complete a pain questionnaire, which they retained and completed on the morning after surgery, before returning it to the authors. Pain assessment was carried out using twin 10-cm vertical visual analogue scales (VAS), one for each operation side. Anchor points were 0=no pain, 100=worst pain possible. A long form McGill pain questionnaire was also completed on the morning after surgery. Patients were requested to complete the VAS on the left of the page for left-sided pain and the VAS on the right side of the page for right-sided pain. Then they completed a single McGill pain questionnaire by placing the letters L (left), R (right) or R+L (both sides) beside the words which described the sensation which they experienced on the day after surgery.

The procedure was carried out under general anaesthesia. Anaesthesia was induced with propofol and maintained with 1.5% halothane and 60% nitrous oxide in oxygen during spontaneous

---

W. I. CAMPBELL, MD, FFARCSI (Department of Anaesthetics); R. W. KENDRICK, MB, FDSRCPS, FFDRCSI (Department of Oral Surgery); The Ulster Hospital, Dundonald, UNDAH Trust, Belfast BT16 0RH. Accepted for publication: June 19, 1997.

Correspondence to W. I. C.

breathing via a nasal tracheal tube. Surgery was commenced on the right side in the first 20 consecutive patients and on the left side in the subsequent 20 consecutive patients. The same surgeon operated on both sides, and if more difficulty was experienced on one side that patient was excluded. Surgical difficulty was rated by the surgeon after operation as: I=simple elevation; II=bone removal or tooth division; III=bone removal and tooth division; IV=very difficult. Postoperative analgesia comprised co-codamol (codeine 8 mg and paracetamol 500 mg), two tablets 4-hourly, as required.

Another 40 ASA I and II patients were studied and written informed consent was obtained in each case. These patients were given a pain questionnaire and instructed on its use after surgery, as described earlier. This pain questionnaire had two VAS to be completed 6 h after surgery, on the morning after surgery and 6 days after operation. A McGill pain questionnaire was included with the VAS to assess pain on the morning after surgery. All pain assessments were to be completed, as during the first part of the study, and posted back to the authors.

General anaesthesia was carried out as in the first part of the study, except that perioperative local anaesthesia was also used. Restricted randomization was carried out using shuffled, sealed envelopes to allocate patients to one of two groups. Group A received an inferior alveolar and a long buccal nerve block, using 0.5% plain bupivacaine 2 ml at each site, on the left side only. If the upper third molars were also to be removed, buccal infiltration with 0.5% plain bupivacaine 1 ml was administered on the left side. Surgery then commenced on the right (contralateral) side and when this was complete local anaesthetic was injected as above on this side. Those patients allocated to group B were treated in an identical manner to those in group A but the sides treated with local anaesthetic before or after surgery were reversed.

The purpose of the above procedure was to establish two groups, each of 20 patients, one with surgery commencing on the right and the other with surgery starting on the left side. Regardless of the grouping, the first side operated on was always the side which was blocked by local anaesthetic after exodontia. Surgery did not start on the second side until at least 10 min had elapsed after pretreatment with bupivacaine. A gradual decline in heart rate on completion of surgery on the first side, and lack of sympathetic response on starting surgery on the second side helped confirm adequate local anaesthetic block before surgery started on the second side.

Both the anaesthetist and patient were blinded as to the side which was pretreated. If surgery was more difficult on one side or patients were not bilaterally numb and pain free, they were excluded from the study and their randomization envelope reallocated to the next available patient who met the entry criteria for the study.

The Wilcoxon matched pairs signed rank test was used to compare individual differences in VAS and McGill pain questionnaire scores. The Mann–Whitney *U* test was used to test for differences in pain associated with the first side operated on, dominant hand and difficulty of surgery. The 5% level of significance was used throughout.

Thirty women and 10 men were observed in the first part of the study: mean age was 23 (range 18–32) yr and mean weight 65 (SD 11.9) kg. The number of patients within each difficulty of surgery grading (I, II, III and IV) was two, 13, 22 and three, respectively. There was no relationship between pain intensity and difficulty of surgery, or between pain intensity and the first side operated on. In four cases, the dominant hand was the left, and the first side operated on was the dominant side in 18 cases. Pain scores were not dependent on the dominant side. There was no significant difference in pain intensity, as assessed at 24 h with either VAS or McGill pain questionnaires (table 1). From these results it was determined that at least 30 subjects would be required if a similar study design was used to evaluate analgesia, to achieve a difference of 10 mm and 90% power at the 5% level of significance.

Thirty-one women and nine men took part in the second part of the study but two women were excluded from group A; one because of unilateral excessive bleeding and the other because of unilateral infection after operation. Mean age was 23 (range 18–41) yr and mean weight was 65 (SD 9.7)

Table 1 McGill pain questionnaire and visual analogue scale pain ratings for the first and second side operated on in patients undergoing bilaterally symmetrical lower third molar extraction under general anaesthesia alone ($n=40$). Medians (interquartiles) are also given for the difference in pain rating between the two sides in each individual (second minus first side scores.) There was no significant difference between the two sides, using either form of pain assessment, on the morning after surgery

	Median (interquartiles)
Pain assessment on the morning after surgery	
Visual analogue scale	
First side	18 (7.3, 36.8)
Second side	18 (13.3, 39.8)
McGill pain questionnaire	
First side	9 (4.3, 15)
Second side	10 (6.3, 15)
Difference in pain assessments between sides on the morning after surgery (second minus first side)	
Visual analogue scale	1.0 (−1.5, 7.8)
McGill pain questionnaire	0 (0, 1.0)

Table 2 Difference in pain ratings between the first and second side operated on in patients ($n=38$) undergoing bilaterally symmetrical lower third molar extraction under general anaesthesia. In each case, patients received local anaesthetic after tooth extraction on the first side and local anaesthetic 10 min before tooth extraction on the second side. There was no significant difference in pain between the two sides at any time after surgery

Differences in measured pain intensity (second minus first side)	Median (interquartiles)
Visual analogue scale differences at	
6 h	0 (−8.8, 5.3)
1 day	0.5 (−8.3, 5.0)
6 days	0 (−2.0, 2.5)
McGill pain questionnaire differences at	
1 day	0 (−1.0, 0.3)

kg. The number of patients within each difficulty of surgery grading (rated I–IV) was six, 19, 9 and four, respectively. Pain intensity did not correlate with difficulty of surgery or the first side operated on. All data were therefore pooled and the difference in pain between the first and second sides operated on in each patient used to establish if there was an overall meaningful difference in pain intensity (table 2). There was no significant difference in pain at any time between the two sides.

Comment

Animal research over the past few decades has demonstrated the benefits of analgesic treatment before rather than after noxious stimulation.[1] Recent clinical work has not confirmed these potential benefits[3] and it is uncertain whether or not pre-emptive analgesia occurs as a clinically useful entity. It may well be that local anaesthesia only postpones the time at which central sensitization takes place.[6]

Our initial study was established to determine the validity of using each patient as their own control. Although similar bilateral studies have been carried out in the clinical situation in the past, patients were not acting as their own controls at the same moment.[7 8] This study was designed to do this but general anaesthesia was required to assess the efficacy of local anaesthesia. Our technique is limited in that only "single shot" treatments can be tested, as subsequent treatments affect both sides, reducing the response difference. Bilateral symmetrical surgery could, however, be carried out under local anaesthesia to study the pre-emptive effectiveness of i.v. analgesics, for example non-steroidal anti-inflammatory drugs, if administered after commencing surgery on the first side.

Although the initial study may have minimized variables such as age, sex, race, anxiety and personality, there was still sufficient within-patient variation to require a minimum of 30 subjects. This symmetrical study design probably did not eliminate small differences in surgery and hence tissue damage, despite the procedure being carried out by the same surgeon. We therefore studied well in excess of 30 subjects to ensure sufficient study power.

Although pre-emptive local anaesthesia did not appear to have advantages over postoperative use, it rendered these patients pain free during the first few hours after surgery, when pain would be at its most intense.

Intra-articular morphine and clonidine produce comparable analgesia but the combination is not more effective

M. GENTILI, P. HOUSSEL, M. OSMAN, D. HENEL, A. JUHEL AND F. BONNET

Summary

Both intra-articular morphine and clonidine produce analgesia. This study was designed to compare the analgesic effects of the two drugs, used separately and in combination. We studied 90 patients undergoing arthroscopy of the knee under general anaesthesia. Patients were allocated randomly to receive 20 ml of intra-articular isotonic saline solution containing morphine 2 mg, clonidine 150 μg or both. Pain was assessed on an visual analogue scale after operation and time for rescue medication was measured. There was no difference in VAS scores between the three groups and the time for rescue analgesic was comparable. We conclude that intra-articular morphine and clonidine have comparable analgesic effects in the doses used. The combination of both drugs did not seem to increase analgesia. (*Br. J. Anaesth.* 1997; **79**: 660–661).

Key words
Analgesia, postoperative. Analgesics opioid, morphine. Sympathetic nervous system, clonidine. Analgesic techniques, regional, i.a.

Since the first clinical studies which demonstrated that intra-articular administration of morphine could provide analgesia, related to a peripheral mechanism of action,[1] this technique has become popular and is used commonly to provide analgesia after arthroscopic knee surgery. Morphine has also been combined with bupivacaine to augment analgesia.[2] More recently, clonidine has been shown to provide analgesia when administered into the knee joint after arthroscopy.[3] As subcutaneous administration of clonidine was not effective in producing analgesia, a local mechanism of action was hypothesized.[3] Morphine and clonidine have synergistic analgesic effects when given intrathecally but not i.v.,[4] but the effect of the combination is not known when administered intra-articularly. Therefore, this double-blind, prospective, randomized study was conducted to compare the analgesic effects of morphine and clonidine when used alone and in combination.

Methods and results

After obtaining informed consent and Ethics Committee approval, we studied 90 ASA I–II patients undergoing knee arthroscopy. Surgery was performed under general anaesthesia using propofol 2 mg kg^{-1} and alfentanil 10 μg kg^{-1} for induction, and isoflurane and 50% nitrous oxide in oxygen for maintenance. Patients were allocated randomly in one of three groups according to the analgesic regimen. All received 20 ml of intra-articular isotonic saline solution before tourniquet release containing morphine 2 mg (group M), clonidine 150 μg (group C) or both (group M+C). Pain was assessed after operation using a visual analogue scale (VAS) at 1, 2, 3, 6 and 24 h after intra-articular injection. Patients received propacetamol 2 g i.v. when they complained of pain (VAS >4). Patients were also monitored for arterial pressure, heart rate and sedation, and side effects (nausea, vomiting or pruritus) were also noted.

Data were analysed using the Mann–Whitney *U* test for patient data. Median and ranks of VAS scores were compared using Kruskall–Wallis analysis. The number of patients not given propacetamol was compared using the Kaplan–Meyer method and a log-rank test.

The three groups were comparable in age (group C, 36 (range 19–69) yr; group M, 36 (18–72) yr; group M+C, 36 (20–70) yr), weight (group C, 73 (SD 10) kg; group M, 72 (10) kg; group M+C, 67 (11) kg) and height (group C, 173 (8) cm; group M, 172 (8) cm; group M+C, 171 (9) cm). Group C included 20 men and 10 women, group M, 23 men and seven women and group M+C 19 men and 11 women (ns). Mean durations of surgery were 37 (18) min, 35 (20) min and 30 (13) min in groups C, M and M+C, respectively. VAS scores were comparable in the three groups (fig. 1) but the scores decreased significantly over time. Seventeen patients in the morphine and clonidine groups and 16 in the morphine–clonidine combination group did not receive propacetamol (ns). The number of patients who did not require additional analgesia in the post-operative period was comparable in the three groups. Arterial pressure and heart rate did not change

significantly. No patient complained of sedation or other side effects.

Comment

We have found that intra-articular morphine 2 mg was equivalent to clonidine 150 μg in terms of post-operative analgesia. In all groups, mean VAS scores were low and rescue medication was limited. The hypothesis that a more painful surgical procedure could have elicited a difference between the two study drugs nevertheless cannot be excluded. For this type of procedure (knee arthroscopy) both drugs appeared to provide effective analgesia in the majority of patients although some patients may have experienced a more painful postoperative course despite intra-articular injection.

We did not compare morphine and clonidine with placebo; this comparison has been performed in previous studies and both drugs were demonstrated to be superior to placebo.[1 3] A local analgesic action of morphine is thought to be mediated by axonal endogenous opioid receptors[5] while inhibition of noradrenaline release could explain the analgesic action of intra-articular clonidine.[3] The lack of side effects commonly noticed after i.v., extradural or parenteral administration of drugs confirms that a local action probably accounts for most of the analgesic effect.

When combined, the two drugs were not more effective than each given separately. One possible explanation for the lack of additive effect is that morphine and clonidine induced complete pain relief during the first hours after operation and that no additional effect was required or measurable. Nevertheless, 50% of patients received pro-pacetamol at some time during the study, implying that analgesia could be potentially improved. We conclude that small doses of morphine or clonidine provided comparable analgesia after intra-articular administration, but that the combination of these doses of the two drugs would not be useful.

Autotransfusion in major orthopaedic surgery: experience with 1785 patients

B. Borghi, E. Pignotti, M. Montebugnoli, A. Bassi, M. Corbascio, N. de Simone, K. Elmar, U. Righi, A. M. Laguardia, S. Bugamelli, F. Cataldi, R. Ranocchi, M. A. Feoli, T. Bombardini, G. Gargioni, A. G. Franchini and G. C. Caroli

Summary

Using a prospective audit, we have evaluated the efficacy of an integrated autotransfusion regimen which comprised predepositing and intra- and postoperative blood salvage in major orthopaedic surgery. We examined prospectively the records of 1785 patients (1198 females, 5867 males, mean age 62 (range 16–90) yr, preoperative haemoglobin concentration 13.4 (SD 1.4) g dl^{-1}) undergoing total hip arthroplasty (THA, 1229 patients), THA after removal of internal fixation devices (RFD+THA, 18 patients), total knee arthroplasty (TKA, 263 patients), revision surgery of the hip (HR cup+stem revision, 197 patients; cup revision, 53 patients; stem revision, 16 patients) and total knee revision (TKR, nine patients). We estimated that the number of predonations (MSBOS=maximum surgery blood order schedule) was 2 u. for THA, TKA and TKR, and 3 u. for partial or total hip revision and total hip arthroplasty with fixation removal. We found that it was possible to obtain the MSBOS in 1597 patients (89.5%). Homologous red blood cell (HRBC) transfusions were carried out in 131 patients (7.3%). We found that the need to use HRBC was significantly associated with failure to meet the number of MSBOS, female sex, lower preoperative haemoglobin concentration, use of calcium heparin for antithrombosis prophylaxis, more extensive surgery, higher ASA rating and co-existing diseases such as coronary artery disease. (*Br. J. Anaesth.* 1997; **79**: 662–664).

Key words
Blood, transfusion. Transfusion, autotransfusion. Blood, salvage. Anaesthesia, audit. Surgery, orthopaedic.

Autologous blood transfusions are used widely to decrease the risk of homologous blood transfusion. The techniques used in autotransfusion for major orthopaedic surgery include predonation of blood, haemodilution and intra- and postoperative recovery of red cells for re-transfusion.[1 2]

This prospective audit was designed to examine the success rate of a regimen devised in our institution for autotransfusion in major orthopaedic surgery based on predonation of blood and intra- and postoperative recovery. Our policy dictates that 2 u. of predonated blood should be obtained for total hip arthroplasty, total knee arthroplasty and total knee revision, and 3 u. are required for partial or total hip revision and for total hip arthroplasty with fixation removal. We termed these requirements the maximum surgery blood order on schedule (MSBOS). During predonation and the first week after surgery, iron is administered i.v. During surgery, uncoagulated blood is collected into a reservoir using an aspirator and collection bag connected to the inferior edge of the surgical wound. If there is a decrease in haemoglobin concentration of more than 2 g dl^{-1} (or even lower when the risk of homologous transfusion is very high, for example patients with anaemia, coronary heart disease or low body weight),[2] a kit is attached to the reservoir to concentrate, wash and reinfuse red cells (Compact-A Dideco, Mirandola MO, Italy). In the postoperative period, bleeding is monitored using the BT797 recovery Dideco and if postoperative blood loss exceeds 200 ml for the first 8 h after sedimentation and microfiltration, red cells are reinfused. The predonated blood is reinfused over the first 3 days after surgery in order to compensate for the decrease in haemoglobin concentration which normally occurs in this period.[2]

Homologous red concentrated red cells (HRBC) are transfused only when correcting hypovolaemia, when autologous blood has been reinfused, when symptomatic anaemia is present (vertigo, dizziness, postural hypotension, headache, insomnia, confusion, tachycardia, angina, dyspnoea) or when haemoglobin concentration decreases to less than 6 g dl^{-1} (10 g dl^{-1} in patients affected by cerebrovascular or coronary artery disease).

Methods and results

We studied 1785 consecutive patients (1198 females and 578 males) in three departments of the Rizzoli

Orthopaedic Institute, Bologna, Italy. Mean age of the patients was 62 (range 16–90) yr and mean preoperative haemoglobin concentration was 13.4 (SD 1.4; range 6.7–18) g dl^{-1}. The types of surgery comprised total hip arthroplasty (THA, 1229 patients) THA after removal of internal fixation devices (RFD+THA, 18), total knee arthroplasty (TKA, 263 patients), total hip revision (cup+stem THR, 197 patients), cup revision (cup R, 53 patients), stem revision (stem R, 16 patients) and total knee revision (TKR, nine patients).

General anaesthesia was administered to 1182 patients and extradural with general anaesthesia to 595 patients. Eight patients received spinal anaesthesia. A total of 119 patients were classified as ASA I, 1144 as ASA II, 486 as ASA III and 36 as ASA IV. In this study 1384 (77.5%) patients had co-existing disease; 809 (45.3%) had a body mass index of 28–33 kg m^{-2}; 23 (1.3%) were obese (BMI >33 kg m^{-2}); 423 (23.7%) had systemic hypotension; 249 (13.9%) chronic obstructive airways disease; 216 (12.1%) coronary artery disease (CHD); 98 (5.5%) diabetes; 75 (4.32%) cardiac arrhythmias; 67 (3.7%) previous deep vein thrombosis or pulmonary thromboembolism; 62 (3.5%) liver disease; 43 (2.4%) rheumatoid arthritis; 33 (1.8%) cardiac valvular disease; 32 (1.8%) renal disease; 9 (1%) transient ischaemic attacks; and 25 (1.4%) anaemia (haemoglobin concentration <10 g dl^{-1}). There was no co-existing disease in 401 (22.5%) patients. For antithrombotic prophylaxis, calcium heparin (Ca He) was given to 267 patients, low molecular weight heparin (LMWH) to 230 patients and indobufen (antiplatelet agents) to 1286 patients. Two patients suffered from coagulation disorders and did not receive therapy.

Data were analysed statistically using SPSS 6.1 for Windows with contingency tables with Fisher's exact test (CT), contingency tables with Pearson chi-square test (CPT), and one-way analysis of variance with Levene test for uniformity of variances (ANOVA).

It was possible to obtain the required number of predonations (MSBOS) in 1957 patients (89.5%). In the other 188 patients (10.5%), the preoperative haemoglobin value did not allow us to achieve the target number of predonations. Mean basal haemoglobin concentration was significantly lower in the no MSBOS group (12.6 (SD 12.5) g dl^{-1} *vs* MSBOS 13.5 (1.4) g dl^{-1}) (ANOVA <0.001)). A total of 131 (7.3%) patients received homologous red blood cell transfusions (HRBC). The need for HRBC was influenced by the following: number of predonations (MSBOS 5% (80 of 1517) of patients compared with no MSBOS (27.1%; 51 of 137 patients) (CT, P=0.0001)); sex (females 8.6% *vs* males 4.8%) (CT, P<0.0049)); low baseline haemoglobin concentration (12.3 (SD 1.6) *vs* 13.5 (1.3) g dl^{-1}) (ANOVA, P<0.0001)) (fig. 1); age (67.8 (9.9) *vs* 62.1 (11.3) yr) (ANOVA, P<0.0001)); higher ASA status (IV 18.7% *vs* III 10.1% *vs* II 6.6% *vs* I 0%) (CPT, P=0.0001)); and co-existing disease (CHD 15.7 *vs* no CHD 6.2%) (CT, P<0.0001)). Thirty-two (0.7%) patients were transfused with HRBC because of haemorrhage or haematoma.

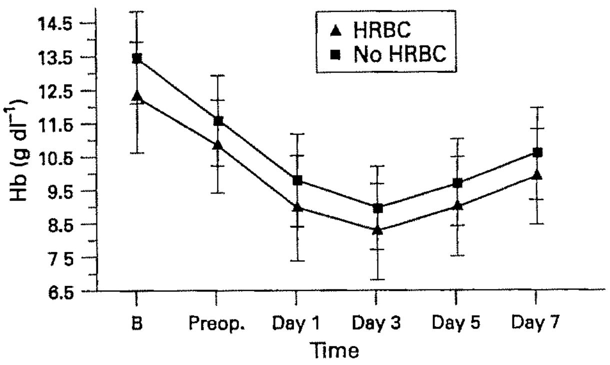

Figure 1 Perioperative changes in haemoglobin (Hb) concentration in patients treated with homologous red blood cells (HRBC) or without (No HRBC) (mean, SD). B=Baseline.

The numbers of patients treated with intraoperative salvage and postoperative salvage are shown in table 1. Administration of HRBC correlated with the type of surgery (THR 16.2% *vs* cup R 11.3% *vs* RPS+THA 11.1% *vs* stem R 6.2% *vs* THA 6.1% *vs* TKA 5.7% *vs* TKR 0%) (CTP, P=0.0001)), ASA group (ASA IV 18.7% *vs* III 10.1% *vs* II 6.6% *vs* THA 6.1% *vs* TKA 5.7% *vs* TKR 0%) (CTP, P=0.0001)), type of antithrombotic prophylaxis (Ca He 18% *vs* LMWH 7.8% *vs* indobufen 5%) but was not influenced by the type of anaesthetic, duration of surgery, amount of intra- and postoperative recovery of blood, extent of postoperative blood loss or interval between the last donation and surgery.

In 85 patients without cerebrovascular disease or ischaemic heart disease and a haemoglobin concentration greater than 11 g dl^{-1}, some of the predonated blood was not reinfused. Patients who underwent HRBC had significantly lower perioperative haemoglobin values (ANOVA, P=0.0001) (fig. 1).

Table 1 Number (%) of patients studied, and number treated with intraoperative salvage (IOBS), postoperative salvage (POBS) and homologous red blood cells (HRBC). Mean (SD) IOBS, POBS and postoperative blood loss (POBL)

Comment

The Compact-A Dideco apparatus used in our institution causes less damage to red cells than cells predonated in SAG-M and kept in the refrigerator for 21 days at 4 °C,[3] and enables a higher concentration of 2,3 diphosphoglycerate and higher physiological concentration of potassium than the donor's blood[4] and explains the absence of any correlation between the amount of intra- and postoperative blood loss and use of HRBC. Other workers have reported the use of autologous blood alone in 28–62% of cases for this type of surgery by only carrying out predepositing.[5 6] With the use of only intraoperative blood salvage, it has been reported that in 28–90% of cases, autologous blood alone was used.[7 8] Where predisposition, intraoperative salvage and postoperative salvage were used in combination, autologous blood was used exclusively in 83–93.7% of cases.[1 2 9] When patients have low preoperative haemoglobin concentrations, it may be possible to use human erythropoietin to increase the amount of blood which may be obtained in advance of surgery in order to decrease the extent of homologous red cell transfusion.[10]

We conclude from this prospective evaluation of our policy for autotransfusion that red cell predisposition and intra- and postoperative salvage in combination is an effective technique for avoiding the use of homologous red cell transfusion.

Continuous intra-arterial blood-gas monitoring in infants and children with cyanotic heart disease

M. HATHERILL, S. M. TIBBY, A. DURWARD, V. RAJAH AND I. A. MURDOCH

Summary

We have evaluated the accuracy and reliability of the Paratrend 7 continuous blood-gas analyser in infants and small children under conditions of severe hypoxaemia admitted to the paediatric intensive care unit in the perioperative period with cyanotic congenital heart disease. P_{O_2}, P_{CO_2} and pH (hydrogen ion concentration) were measured continuously via a femoral arterial sensor and compared with 100 simultaneous paired arterial blood-gas measurements. Data were analysed by Bland–Altman analysis for bias and precision. Sensors were placed in 10 children of median age 5.43 (range 0.03–45) months, median weight 3.74 (2.79–15.4) kg and remained in place for up to 27 h after operation. P_{O_2} values were 2.5–8.2 kPa (median 5.3 kPa). Co-oximeter saturation ranged from 37.1% to 90.6% (median 75.8%). Bias and precision values were 0.04/0.87 kPa for P_{O_2}, −0.44/0.74 kPa for P_{CO_2} and −2.61/6.98 nmol litre^{-1} for hydrogen ion concentration (i.e. 0.02/0.06 for pH). We conclude that perioperative continuous arterial gas monitoring is clinically accurate under conditions of severe hypoxaemia in small infants and children with cyanotic congenital heart disease. (*Br. J. Anaesth.* 1997; **79**: 665–667).

Key words
Hypoxaemia. Heart, congenital defects. Infants. Children. Monitoring, blood gases. Equipment, gas analysers.

Continuous intra-arterial blood-gas monitoring has been available in adult anaesthesia and intensive care for several years, although routine use is limited to a few centres.[1 2] The clinical use and accuracy of the Paratrend 7 system (Biomedical Sensors, High Wycombe, UK) has been established previously in humans and recent reports have documented the experience of continuous blood-gas analysis in children.[2 3]

In paediatric practice, application of this technology is likely to have maximum impact in paediatric intensive care units and operating theatres. Children undergoing cardiac surgery are one group likely to benefit from continuous monitoring, especially in the perioperative and immediate postoperative periods. However, there is a paucity of data on the accuracy of such systems under the condition of severe hypoxaemia, commonly present in children with cyanotic congenital heart disease. As previous studies have excluded smaller children and infants, there is also a lack of data on the safety and reliability of these devices in these patients.[3–5]

We present our experience of perioperative continuous intra-arterial blood-gas monitoring using the Paratrend 7 system in small infants and children with cyanotic heart disease.

Methods and results

The study was approved by the Hospital Ethics Committee. We studied children admitted to the paediatric intensive care unit (PICU) with severe hypoxaemia caused by cyanotic congenital heart disease. Only patients in whom continuous blood-gas monitoring was indicated for clinical reasons were recruited. These included infants admitted for correction of congenital cardiac defects in whom the sensor was sited before operation and children admitted after cardiac surgery and cardiopulmonary bypass in whom it was sited in the immediate postoperative period. Because of the small size of the patients, the sensor was left *in situ* for the first day after operation only, as a precautionary measure.

The Paratrend 7 sensor is a heparin-bonded element which consists of a modified Clarke electrode measuring P_{O_2}, a fibreoptic system and chemical indicator complex for measurement of P_{CO_2} and pH (hydrogen ion concentration), and a thermocouple for measurement of temperature. Oxygen saturation and base deficit are calculated. *In vitro* 90% response times for changes in pH, P_{CO_2} and P_{O_2} are reported to be 78, 143 and 70 s, respectively.[2] The sensor itself is less than 0.5 mm in diameter and is advanced within a closed-system connection via a 20-gauge cannula into the femoral artery.

Arterial pressure is transduced via a Y-connection to the device through which arterial blood is sampled in the usual manner. During the study the arterial pressure waveform was monitored for evidence of

Table 1 Data for children monitored by continuous intra-arterial blood-gas analyser

Patient No.	Diagnosis/procedure	Age (months)	Weight (kg)
1	Hypoplastic left heart (HLHS)	0.03	2.7
2	HLHS/ Norwood Stage 1	0.1	2.9
3	HLHS/ Norwood Stage 1	0.03	3.2
4	HLHS/ Norwood Stage 1	0.03	3.7
5	Fallot's repair	9.6	3.7
6	Transposition of great arteries	1.2	3.7
7	Glenn shunt	15.7	8.6
8	Glenn shunt	17.8	9
9	Glenn shunt	29.8	9.6
10	Glenn shunt	45	15.4

cannula malfunction and the limb assessed continuously for evidence of ischaemia.

We studied 10 infants and children, median age 5.43 (interquartile range (IQ) 0.05–17.09; range 0.03–45) months, median weight 3.74 (IQ 3.33–8.92; range 2.79–15.4) kg (table 1).

Ten paired blood-gas measurements were made per patient, using the read-out from the Paratrend and a simultaneous arterial blood-gas (ABG) sample analysed at patient temperature (1420 Blood Gas Analyser, Instrumentation Laboratories, Birchwood, UK). The coefficients of variation for the bench ABG analyser are given as 2.1%, 6.4% and 13% for P_{O_2}, P_{CO_2} and pH, respectively. Hydrogen ion concentration was calculated from the measured pH values for the purpose of statistical analysis. Oxygen saturation calculated by the Paratrend was compared with paired measurements obtained by co-oximetry (682 Co-oximeter, Instrumentation Laboratories) and pulse oximetry (M1020A/66S Pulse oximeter, Hewlett Packard, Berkshire, UK).

The manufacturers provide a facility to correct the Paratrend read-out for "perceived bias" if readings are consistently different from simultaneous ABG values after prolonged use. This facility has been used in previous studies evaluating the bias and precision of the system, but was not used in this study.[2]

Bias and precision were calculated as the mean difference between the paired measurements, and the limits of agreement (2 SD) of these differences. Data were analysed graphically by Bland–Altman analysis, and by linear regression for historical comparison.[6]

One hundred paired measurements were performed up to 27 h after insertion of the sensor. Oxygen saturation measured by co-oximetry ranged from 37% to 90% (median 75.8%; IQ 66.7–82.6%). P_{O_2} measured by the ABG analyser was 2.5–8.2 (median 5.3; IQ 4.3–6.2) kPa. P_{CO_2} was 2.71–7.09 (median 4.76; IQ 4.44–5.19) kPa. pH was 7.14–7.59 (median 7.39; IQ 7.37–7.44).

Bias and precision values for P_{O_2} were 0.04/0.87 kPa (r^2=0.64) (fig. 1). Variation in ABG/Paratrend P_{O_2} difference did not increase with duration of insertion of the sensor or at extremes of haemoglobin concentration. Bias and precision values were −0.44 /0.74 kPa (r^2=0.76) for P_{CO_2} and −2.61/6.98 nmol litre^{-1} (r^2=0.89) for hydrogen ion concentration (i.e. 0.02/0.06 for pH).

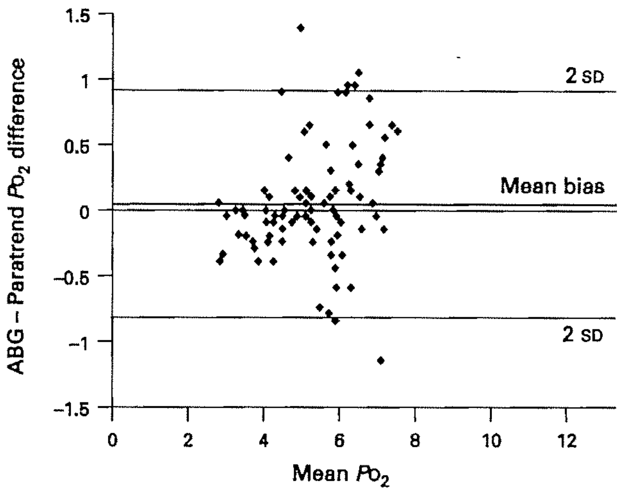

Figure 1 Bland–Altman anaysis of bias and precision for P_{O_2} (kPa) measured by the ABG and Paratrend (mean (±2 SD)).

Bias and precision values for oxygen saturation calculated by the Paratrend and measured by co-oximetry were 2.4/9.5% compared with 0.2/4.3% for oxygen saturation measured by pulse oximetry and co-oximetry.

Sensor malfunction, presumably caused by kinking as a result of patient handling, resulted in removal of the sensor in two children after 11.5 and 18.5 h, respectively. One patient with hypoplastic left heart syndrome in whom the sensor was placed before operation later developed necrotizing enterocolitis and died after stage 1 Norwood operation.

Comment

The ability to monitor continuous changes in arterial blood-gas variables is of particular interest to anaesthetists and intensivists involved in the management of children before, during and after complex cardiac surgery. Many of these patients undergo surgery for correction of cyanotic heart disease during the first year of life, underlining the importance of a continuous intra-arterial system which is accurate and reliable both in small infants and under conditions of severe hypoxaemia.

The benefits of an indwelling continuous sensor in the perioperative period include the ability to respond promptly to acute cardiovascular or ventilatory changes, minimization of blood loss in small infants and reduction of the risk of infection.

Previous studies have evaluated the clinical accuracy of the Paratrend sensor in adults and older children.[1–5] However, several of these studies included methodological errors related to correction of "perceived bias" during the study period and the use of large numbers of measurements in a single patient.[2 3] We performed 10 paired measurements in each patient and did not adjust measurements to correct for perceived bias during the study, although this may be indicated after prolonged insertion (beyond 24 h) in the clinical setting.

The bias and precision (limits of agreement or 2 SD) of the sensor demonstrated clinically acceptable accuracy for measurement of pH (H$^+$), P_{CO_2}

and $P\mathrm{O}_2$ under conditions of severe hypoxaemia ($P\mathrm{O}_2$ <8 kPa). The limits of agreement for $P\mathrm{O}_2$ in this study were 0.87 kPa, which compares favourably with the results of previous studies (single SD) which ranged from 0.91 to 3.4 kPa. Our results did not reflect the higher variability of $P\mathrm{O}_2$ measurements compared with $P\mathrm{CO}_2$ and pH reported by other workers. Previous authors have reported a single SD ranging from 0.53 to 0.81 kPa for $P\mathrm{CO}_2$ and from 0.024 to 0.06 for pH.[1–5] Although our study included only the first post-operative day, there did not appear to be any decay in the precision of $P\mathrm{O}_2$ measurement with time. Further studies of cyanotic infants, including larger patient numbers and longer insertion times, are necessary to confirm this finding. There was no deterioration in accuracy for $P\mathrm{O}_2$ measurement at either high or low extremes of haemoglobin concentration. The bias and precision of oxygen saturation calculated by the continuous analyser compared favourably with that of previously published work in cyanotic patients.[7,8] However, we were surprised to find that calculated oxygen saturation appeared less accurate than that measured by pulse oximetry in this group.

Our study population was both younger and smaller (<10 kg) than those previously reported. There were few problems with femoral artery access or introduction of the sensor, even in patients weighing less than 5 kg. The sensor failure rate (two of 10) was acceptable considering the learning phase involved in the introduction of a new technique, and can be minimized by careful patient handling.

We conclude that continuous indwelling blood-gas analysis using the Paratrend system is practical, reliable and clinically accurate in infants with cyanotic heart disease.

CASE REPORTS

Extradural catheter-related infections in patients with infected cutaneous wounds

M. Bengtsson, H. Nettelblad and F. Sjoberg

Summary

We report three previously healthy individuals, aged 19–40 yr, with co-existing infected lower limb cutaneous wounds, who developed, in all probability, spinal space infections complicating continuous extradural analgesia. As the number of patients with extradural catheters and large cutaneous wounds represents a small fraction of the total number of patients with extradural catheters, three cases of presumed spinal space infection over a 4-yr period suggests that extradural analgesia with a catheter technique in this clinical situation is unsafe.

Key words
Anaesthetic techniques, extradural. Infection, spinal. Equipment, catheters extradural.

In a recent article by Jakobsen, Christensen and Carlsson,[1] it was concluded that extradural analgesia with a catheter technique is "a relatively safe procedure" in the surgical treatment of abscesses or infected wounds. Our experience is different. Between 1991 to 1995 we encountered three trauma patients with large open cutaneous wounds who developed, in all probability, spinal space infections after extradural catheter analgesia. Taking into account the small referral area (approximately 1 million inhabitants), the risk of developing an extradural infection may be higher than anticipated previously. A summary of the data from these three cases is given in table 1. (*Br. J. Anaesth.* 1997; 79: 668–670).

Case reports

CASE NO. 1

A 20-yr old, previously healthy farmer sustained a traumatic amputation of his right leg at thigh level combined with major blood loss. After initial resuscitation at a nearby hospital an extradural catheter was inserted at the L3–4 interspace on the second day. At this time the large cutaneous wound in the thigh showed clinical signs of infection and he had an increased white blood cell count of 18.0×10^9 litre^{-1} and a temperature of almost 39 °C. Cefuroxime and clindamycin were commenced. In the skin area above the right hip another cutaneous wound, 3×7 cm, was found. At the time of the second wound revision, the second day after the trauma, the extradural catheter was changed and a new extradural catheter was inserted at the T12–L1 level. Bupivacaine 0.25% and adrenaline 1:200 000 with the addition of sufentanil were delivered via the catheter at a constant infusion rate. There were signs of an ongoing coagulopathy as platelets decreased to 100×10^9 litre^{-1}, activated partial thromboplastin time increased to 45 s (normal range 23–34 s) and prothrombin complex decreased spontaneously to 40% (normal range 70–180%). The wounds were revised a third time. As the status of the patient did not improve, he was transferred to the Department of Plastic Surgery, Linkoping University Hospital on the sixth day after injury. On arrival the patient had a temperature of 40 °C with pain at the site at which the second extradural catheter had been inserted and a stiff neck. The puncture site was found to be red. Antibiotic therapy was changed to cefotaxime. Computer tomography (CT) scan (without contrast medium) was normal, apart from gas bubbles in the spinal canal, but lumbar puncture and analysis of cerebrospinal fluid showed an increased lactate concentration of 4.6 mmol litre^{-1} (reference value <2.1 mmol litre^{-1}). However, direct microscopy of cerebrospinal fluid did not reveal any bacteria or fungi but showed a significant amount of white cells. Simultaneous cultures from the tip of the extradural catheter, the large cutaneous hip wound and urinary tract yielded significant growth of *Pseudomonas aeruginosa*. After removal of the extradural catheter the patient's status improved significantly and by the next day he had a normal temperature. Signs of meningism disappeared simultaneously.

CASE NO. 2

The right foot of a previously healthy 40-yr-old man was crushed in a log-splitter. He was treated initially at a local hospital. Twelve days after injury he was referred to the University Hospital for skin coverage

Table 1 Clinical and bacteriological summary. NI=Not investigated

Patient No.	Duration of catheterization	Presumed infection	Organism isolated from		Sequelae
			Catheter tip	Skin wound	
1	6 days	Meningitis	*P. aeruginosa*	*P. aeruginosa*	None
2	3 days	Abscess	NI	NI	Back pain
3	16 days	Abscess	*S. aureus*	*S. aureus*	None

of the open wound at the site of the partially amputated fore foot. As he was developing phantom pains, an extradural catheter was inserted at the L3–4 interspace and continuous infusion of 0.25% bupivacaine given. Two days later a leak was observed around the catheter. At the same time the patient complained of pain radiating from the region in which the catheter was inserted through the skin. The pain increased the following day. At this point a major wound revision was performed and a split thickness skin graft was applied to the fore foot. The following day dicloxacillin was given as his temperature had increased to 39 °C and the pain from the back area had increased, radiating to the right thigh. The patient also complained of intense headache. The puncture site around the extradural catheter was red and slightly swollen. Suspecting an extradural infection, we changed from dicloxacillin to cefuroxime treatment and removed the extradural catheter. Analysis of cerebrospinal fluid showed a white cell count of 124×10^6 litre^{-1} (normal value 0–5×10^6 litre^{-1}). Unfortunately cultures were not taken at this point. As the patient's body temperature increased further, the next day magnetic resonance tomography (MRT) with contrast medium was performed. MRT (T1-weighted images) showed a process starting from the subcutaneous area extending intraspinally between the spinous processes of L3 and L4, measuring $15 \times 30 \times 25$ mm and dislocating the dura in the right portion of the spinal canal. There was no contrast enhancement in the central part of the process, indicating pus. The neurosurgeon recommended conservative treatment. The status of the patient improved slowly over the following 3 or 4 days. However, during the postoperative period the patient complained of radiating pain in his lower back, still a complaint 2 yr after the injury.

CASE NO. 3

A few days after arthroscopy of her left knee a 19-yr-old woman developed significant iatrogenic lymphoedema. Four months after operation she developed painful opioid-resistant infected ulcers on her left foot requiring vancomycin treatment. Seven months after arthroscopy, a tunnulated extradural catheter was inserted at the L3–4 interspace through which 0.25% bupivacaine and morphine were given. Eleven days after insertion of the catheter the patient had a pyrexia (39.7 °C). On day 14 after catheter insertion the patient had increasing pain radiating out from the back. A culture from the tip of the now withdrawn extradural catheter revealed *Staphylococcus aureus*, the same strain that had been cultured from the ulcer on the foot. A CT scan (using contrast medium) showed increased contrast accumulation at the L3–4 intraspinal level extending to the intervertebral holes at the L3–4 level on the right side and a large abscess in the psoas musculature at the L2–5 level. In relation to the paravertebral musculature of the spinal process of the L3 vertebra, cone-shaped contrast enhancement of the extradural catheter track was seen. The next day, under x-ray guidance, this abscess was punctured transcutaneously and drained. Low back pain and septic fever decreased rapidly. The increased white blood cell count and C-reactive protein concentration normalized within 1 week. Unfortunately, the pain problem (in the foot) and the open ulcers continued for another year leading eventually to amputation.

Discussion

We believe that these three cases demonstrate the potentially higher risk of a serious infectious complication after extradural catheter analgesia in patients with infected wounds, in comparison with what has been stated previously[1] or been found in a general intensive care unit population with the well known risk of nosocomial infections.[2] As bacterial cultures showed growth of the same bacterial strains from both the infected wounds and the catheter tips, the likelihood of haematogenous spread between the two sites as a cause of the infectious complication must be regarded as high. None of the cases had open wounds in the immediate vicinity of the puncture site of the extradural catheter, and the catheter was tunnelled in one case. The extradural catheters were inserted by three different anaesthetists, making substandard aseptic technique an unlikely culprit. For these reasons haematogenous spread seems more likely and direct contamination at the puncture site less likely to have been the process responsible. None of the patients was known to have reduced immunocompetence, diabetes mellitus or any other concomitant disease.

Among several reasons for the low incidence of spinal space infections after extradural catheterization one might be antimicrobial activity of the local anaesthetics used. The bactericidal effect is concentration-related and has been shown to be most marked with 0.5% bupivacaine, and less with lower concentrations.[3] Of interest is a study by James and colleagues[4] showing that 0.25% bupivacaine was 5–25 times as potent at 37 °C compared with at room temperature in decreasing the colony count of different bacterial isolates. All of our patients received bupivacaine in a concentration of 0.25% or slightly less (because of dilution by addition of opioid). The extradural solutions were made up by a ward nurse under aseptic conditions using 50-ml syringes that were used immediately and changed in less than 12 h.

The medical management strategy pursued in case No. 2 has been described previously.[5]

The incidence of this type of infectious complication is difficult to evaluate from our material. Whether the previous retrospective investigation of 120 extradurals[1] is to be regarded as too small to determine the true rate of a rare complication is debatable. Our intention is to highlight the fact that these infections do occur and should prompt a high degree of clinical suspicion in any physician responsible for the care of patients with painful open wounds and an extradural catheter. These three cases have also prompted us to restrict the practice of using extradurals in this type of patient.

A case of cardiac hydatidosis

S. LAGLERA, M. A. GARCIA-ENGUITA, F. MARTINEZ-GUTIERREZ, J. P. ORTEGA, A. GUTIERREZ-RODRIGUEZ AND A. URIETA

Summary

We present the case of a female patient with a diagnosis of hydatidosis located in the heart. Although echinococcosis is endemic to our country, very few cases of cardiac hydatidosis are normally reported. In our patient, the hydatid cyst was located in the septum and in the right ventricular cavity; it presented other unusual features, such as the fact that it was located exclusively in the heart, that it first manifested as anaphylactic shock of unknown origin and that it required immediate surgical treatment because of severe haemodynamic compromise. (*Br. J. Anaesth.* 1997; **79**: 671–673).

Key words

Complications, echinococcosis. Complications, hydatidosis. Infection, parasitic.

Echinococcosis is a disease produced by the encysted larvae of echinococcal worms. There are four species pathogenic to human: *E. granulosus*, *E. multilocularis*, *E. oligarthrus* and *E. vogeli*. The most frequent is *E. granulosus* which is endemic in areas of the Mediterranean coast, Middle East, Australia, New Zealand and South America,[1] although it is spreading to other non-endemic countries as a result of immigration.

Echinococcus multilocularis, the causative agent of human alveolar echinococcosis, is found usually in countries of the Northern Hemisphere. *E. oligarthrus* and *E. vogeli* are endemic to Central and South America.

It is agreed that cardiac involvement of echinococcosis occurs in approximately 0.5–2% of all cases, although these values are taken from a study performed in 1958, and are therefore debatable.[2–4] The occurrence of severe complications, such as sudden death and cyst rupture, in cardiac cavities or in the pericardium makes cyst extirpation the most appropriate treatment.

This report describes a case of cardiac hydatidosis and discusses its clinical manifestations, diagnosis, treatment and anaesthetic implications.

Case report

A 49-yr-old female patient with a history of tonsillectomy and brucellosis was admitted suffering anaphylactic shock which had manifested without previous trauma or strain. After treatment at home with adrenaline, dexchlorpheniramine and prednisolone s.c., she was transferred to hospital.

On examination the patient showed signs of low cardiac output and ventricular tachycardia, which was controlled with lignocaine i.v. An ECG performed after remission of symptoms showed ST-segment elevation in leads V1–V3. Chest radiography revealed a small overgrowth of the left ventricular cavity.

Three days after admission, the patient presented with instability, cyanosis, hypotension and a body temperature of 38 °C. The EEG showed subepicardial ischaemia on the anterolateral wall. Echocardiography demonstrated a cystic mass in the interventricular septum with right ventricular cavity collapse. A thoracic computed axial tomography (CAT) scan confirmed the existence of a cystic mass as described by echocardiography and excluded any lung involvement. Abdominal CAT excluded the presence of other cystic masses.

With a diagnosis of cardiac hydatidosis and haemodynamic decompensation, the patient was transferred to a hospital with cardiac surgical facilities. On admission, she was stabilized haemodynamically and she exhibited moderate dyspnoea. Prednisolone 1 g i.v., dexchlorpheniramine 5 mg i.v., ranitidine 50 mg i.v. and midazolam 1.5 mg i.v. were administered 1 h before surgery.

During surgery, we monitored ECG, invasive arterial pressure, central venous pressure and peripheral oxygen saturation. Anaesthesia was induced with midazolam 2 mg, fentanyl 0.2 mg, etomidate 16 mg and vecuronium 6 mg. High-dose vecuronium and fentanyl were given by continuous infusion to maintain anaesthesia, and the lungs were ventilated with 100% oxygen. Surgery was performed under extracorporeal circulation with a 45-min perfusion time and an ischaemia time of 25 min.

The incision exposed an intramyocardial hydatid cyst, 10×7.5 cm, located on the right ventricular

wall and apical septum with leftwards displacement of the anterior interventricular artery. The cyst had ruptured at the apex of the right ventricular chamber with an orifice of 1 cm in diameter. The surgical field was isolated with a protective layer soaked in hypertonic saline solution 20% which was used as a scolicidal agent. On discontinuing cardiopulmonary bypass, the patient required inotropic support (dopamine $5\ \mu g\ kg^{-1}\ min^{-1}$).

The only postoperative complication was paroxysmal supraventricular tachycardia, detected 7 h after surgery. It caused no haemodynamic problems and was treated with amiodarone i.v. ECG revealed complete block of the left branch of His bundle. As soon as oral feeding was restarted, albendazole 400 µg/12 h for 28 days was given. The patient was discharged 9 days after surgery.

Discussion

Echinococcus enters the heart via the coronary circulation, either via a permeable foramen ovale or the pulmonary circulation.[5,6] The embryo reaches full growth at 1–5 yr after being lodged in the heart. The myocardial reaction to the cyst creates an adventitial pericyst layer.[3,5,6]

Although any part of the heart may be affected, the most common location of the cardiac hydatid cyst is the free wall of the left ventricle (50–77%) or the interventricular septal wall. Damage to the pericardium occurs in 50% of cases. Most patients (55–85%) also manifest multivisceral failure involving the liver or lungs, or both, in addition to other organs.[2–4] The disease can remain asymptomatic (90%) but may incidentally result in sudden death.[2–4,7]

Electrocardiographic alterations are not always characteristic of hydatid cysts. However, non-specific disturbances of repolarization, block of the right branch of the bundle of His or atrioventricular node block can occur when the cyst affects the interventricular septum. Septal location of the cyst may cause paroxysmal tachycardia. Cysts lodged in the septum or in the ventricular cavities also cause ventricular arrhythmias. Cysts in the right ventricular cavity may cause right ventricular hypertrophy, whereas those located in the left ventricle usually produce myocardial ischaemia (table 1). Myocardial infarction may occur when the cyst compresses the coronary arteries. Normal electrocardiographic patterns exclude left ventricular wall location.[2,3,6]

Valvular dysfunction
Pulmonary hypertension
Pulmonary embolism
Systemic embolism
Sudden death

Echocardiography is the most efficient method of diagnosing hydatid cysts in the heart.[2,7] Chest radiography can demonstrate signs such as pulmonary cyst, altered cardiac silhouette or traces of calcification that suggest a diagnosis of hydatid cyst. Other diagnostic steps to be taken subsequently include CAT and nuclear magnetic resonance. Further complementary examination may include seeking cysts in other locations using computer image techniques and serological tests.[3]

Before operation, cardiac function should be evaluated using cardiac and coronary angiography as preparation for surgical intervention or in case some form of co-existent valvular or ischaemic lesion is present.[5,6]

Surgery requires cardiopulmonary bypass and moderate hypothermia with aortic cross-clamping. One of the difficulties in the removal of the cyst is its location and extreme fragility. If the cyst is ruptured and there is leakage of content into the systemic circulation, an immunological reaction (type 1 Coombs–Gell response) or an alternative pathway of complement activation may occur, with subsequent liberation of substances which can occasionally cause anaphylactic shock.[8,9] The occurrence of this potentially fatal complication may take place during surgery or early in the postoperative course.[10] Another risk of a ruptured cyst is dissemination. For this reason, surgery should be extremely cautious and the cyst must be isolated from the surgical field and sterilized with saline solution[9,11] or other substances such as 2% formalin, 5% silver nitrate solution, 1% iodine solution, 5% cetrimide solution, hydrogen peroxide or 20–30% hypertonic saline solution.[3]

Fatal cases of cerebral air embolism caused by liberation of gas into the circulation have been reported after sterilization with hydrogen peroxide.[12] Hypertonic saline solution is the least toxic, although it is not free of adverse effects as it may cause hypernatraemia and a case of hyperosmolar coma has been reported.[13]

The combination of corticosteroids with H_1 and H_2 blocking agents, and administration of benzodiazepines are thought to be beneficial in preventing the effects of histamine release.[14] The anaesthetic technique should use drugs with minimal histamine-releasing activity. An anaesthetic regimen combining etomidate, vecuronium and fentanyl has proved highly effective.

With pulmonary cysts, high pressure ventilation must be avoided because of the serious risk of cyst rupture; some authors recommend intubation with double-lumen tubes as the most effective method of isolating the affected lung in case of rupture.[13]

Pulmonary artery catheterization is contraindicated in these patients, although no cases of cyst rupture caused by such catheters have been reported. We believe direct insertion of a catheter by the surgeon to monitor left atrial pressure is preferable.

Supraventricular and ventricular arrhythmias may occur frequently as a result of either the cyst itself or surgical excision, before, during or after operation. Patients in whom anaphylactic shock is suspected as a result of cyst rupture require careful preventive treatment with albendazole or mebendazole to prevent dissemination. Follow-up should include periodic check-ups accompanied by serological and imaging tests.[3] Patients with contraindications to surgery should be treated with mebendazole or albendazole, although their efficiency is uncertain.[2 3 5]

Anaesthesia with intrathecal ketamine: a dose-finding study

C. R. E. Hawksworth* and M. G. Serpell
Western Infirmary, Glasgow

Intrathecal anaesthesia in the elderly population is associated with a high incidence of significant hypotension.[1] Bion used ketamine as the sole intrathecal anaesthetic agent for lower limb surgery and demonstrated a lack of cardiovascular depression which might be advantageous in this population.[2] We undertook a dose-finding study to determine its usefulness as a sole anaesthetic agent for transurethral prostate and bladder tumour resection.

Ten adult male patients ASA status I–III were recruited. Spinal anaesthesia was performed using a 25-gauge Whitacre needle via the L2/3 or L3/4 spaces. A pre-determined dose of preservative-free ketamine (10 mg ml^{-1}) was injected over a period of 30 s. The patient was then placed supine. Sensory and motor block were assessed by pin-prick and a modified Bromage score respectively. The occurrence of nystagmus, dysphoric symptoms or hallucinations were noted. If an adequate block was not obtained, or the block began to wear off during surgery, a general anaesthetic was administered.

The initial dose of ketamine used was 0.5 mg kg^{-1}. This failed to produce any detectable block. The next patient received 0.75 mg kg^{-1} which produced a successful block. Thereafter, a technique of sequential allocation with incremental changes of 0.05 mg kg^{-1} was used. No significant cardiovascular changes were noted. The other results are shown in table 1.

We concluded that intrathecal ketamine at doses of 0 .7 mg kg^{-1} and above produced a sensory and motor block, but the psychomotor side effects and short duration of action precluded its use as the sole anaesthetic agent for routine transurethral urological surgery.

Key words
Anaesthetics intravenous, ketamine.

Effects of low-dose isoflurane on contrast-sensitivity in volunteers

S. R. J. Taylor*, O. A. Khan*, M. Swart* and J. G. Jones
University Department of Anaesthesia, Addenbrooke's Hospital, Hills Road, Cambridge, CB2 2QQ

Many different psychometric tests have been used as a measure of recovery from anaesthesia, including saccadic eye movements and choice-reaction-time tests.[1] However, one test which has not previously been used is contrast sensitivity. We have assessed the effects of isoflurane on subjects' contrast-sensitivity thresholds. This measures the ability of a subject to discern letters from a background when the contrast between the two varies.

Sloan[2] letters were displayed on a high-resolution computer monitor and five healthy subjects were required to indicate which of 10 possible letters they thought had been displayed. Response time was not recorded. An experimental run consisted of 50 such letter trials, displayed in a sequence of pseudo-random contrasts. The resulting data were fitted to the curve

$$P_c=\frac{0.9}{1+(kC)^n}+0.1$$

where P_c indicates the probability of correctly identifying the letter at contrast C, using the Marquardt–Levenberg algorithm, and the contrast at which the subject correctly identified 50% of the letter trials, that is the threshold contrast, was calculated.

Experimental runs were performed for two tests, the first involving the constant appearance of the letter until the subject made his response, and the second flashing the letter onto the screen for $^1/_{72}$ s only (1 frame). These were repeated after the administration of isoflurane in 100% oxygen to achieve an end-tidal concentration of 0.1%.

In all five subjects, administration of isoflurane increased the threshold contrast for both the constant and the flash protocols (fig. 1).

The results showed that isoflurane reduced the contrast sensitivity of the subjects. The dose-dependency of this relationship is currently under investigation.

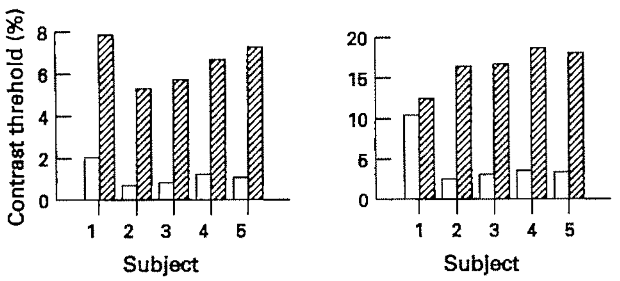

Figure 1 Contrast sensitivity thresholds for the constant letter presentation test (left) and flashed letter test (right) before (open bars) and during (shaded bars) administration of isoflurane to achieve an end-tidal concentration of 0.1%.

Effects of low-dose isoflurane on inhibition of saccadic eye movement

O. A. Khan*, S. R. J. Taylor*, M. Swart* and J. G. Jones
University Department of Anaesthesia, Addenbrooke's Hospital, Hills Road, Cambridge, CB2 2QQ

Saccadic eye movements have been used as a psychometric measurement of recovery from anaesthesia. For example, the peak velocity of these movements has been shown to be depressed in a dose-dependent manner by a number of inhalation anaesthetic agents, including isoflurane, halothane and cyclopropane.[1 2] We have examined the effects of isoflurane on a hitherto unappraised aspect of saccadic eye movements—namely the ability of subjects to inhibit saccadic eye movements through the use of a countermanded saccadic protocol described below.

Measurements of saccadic eye movements were made by a computer-based system[3] using an infrared oculometer. Subjects were seated 50 cm from a 40 cm rectangular LED display. All trials began with the transient presentation of a central fixation point, and after a variable delay, a target appeared at one of two locations at the extremes of the LED display, signalling the subject to make a saccade to the target. In 50% of the trials, the fixation light then reappeared after a 50 ms delay, signalling that the saccade to the target should be inhibited (the stop signal). For each subject the total number of trials was 200 comprised of 100 stop and 100 test signals. The number of occasions when five healthy volunteers failed to inhibit saccades after stop-signal presentation was recorded under baseline conditions, and after administration of isoflurane in 100% oxygen to achieve an end-tidal concentration of 0.1%.

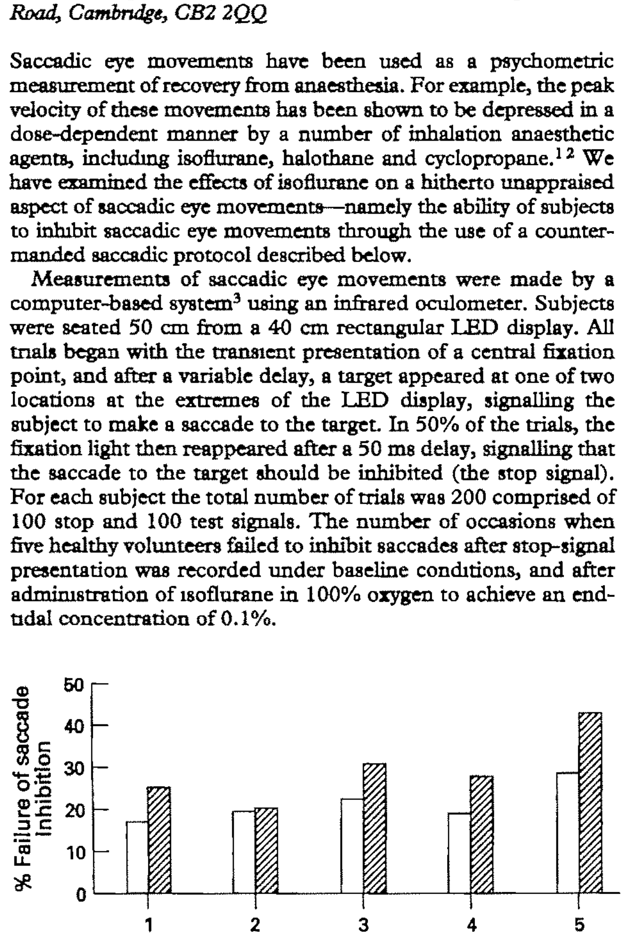

Figure 2 Number of failures to inhibit saccades (as a percentage of total stop signals) under baseline conditions (open boxes) and with isoflurane (hatched boxes) in five subjects.

In all five subjects, administration of isoflurane increased the percentage of occasions when the subjects failed to inhibit saccadic movements after the stop signal (fig. 2).

The results showed that low-dose isoflurane reduced the ability of subjects to inhibit saccades. The dose-dependency of this relationship is currently under investigation.

Outcome of labour using low-dose extradural bupivacaine compared with intramuscular pethidine

P. N. Robinson*, M. Romney*, H. Gordon* and B. A. Loughnan
Departments of Anaesthesia and Obstetrics, Northwick Park Hospital, Middlesex HA1 3UJ

Anaesthetic extradural analgesia is associated with an increased likelihood of obstetric intervention.[1] Current obstetric anaesthetic practice using a weaker solution of local anaesthetic with an opioid is associated with less motor block[2] and may result in a lower incidence of instrumental deliveries. This hypothesis is unproven in the absence of comparison with a non-extradural control. Our study compares the obstetric outcome between primigravidae receiving a "low-dose" extradural mixture and women receiving pethidine.

Written informed consent was obtained from 372 primigravidae in the later stages of uncomplicated pregnancy. Only women uncommitted to any particular form of analgesia were recruited. On admission to the delivery suite in established labour, 110 women opted out of the study, and 71 women required entonox only. A further 38 were excluded. The remaining 153 women were allocated randomly to receive either pethidine 100 mg boluses by i.m. injection (64 patients) or a "low-dose" extradural mixture with fentanyl (89 patients). The extradural regimen consisted of an initial dose of 0.125% bupivacaine 10 ml, and fentanyl 50 μg, with further 10-ml top-ups of a mixture of 0.1% bupivacaine with fentanyl 2 μg ml^{-1}. Rescue analgesia using the same extradural regimen was available to the pethidine group. The management of labour was standardized according to the criteria for the active management of labour.[3] Pain relief scores were assessed 24 h after delivery by the mother on a 5-point verbal rating scale. The main outcomes measured were the mode of delivery and duration of first and second stages. Statistical analysis was performed on the three groups (extradural, pethidine and extradural supplementation of pethidine) using analysis of variance (ANOVA), chi-square test, and Pearson's chi-square test as appropriate.

Twenty-six women in the pethidine group (40.6%) required an extradural for uncontrolled pain. Of those mothers who received pethidine as their sole analgesic in labour, 31 (82%) had a normal vaginal delivery compared with 45 (51%) and 10 (31%) in the extradural and the pethidine plus extradural groups respectively. Mode of delivery was associated with method of analgesia received (chi-square=6.64, $P<0.03$). Use of a "low-dose" extradural was associated with a lower incidence of spontaneous vaginal delivery or low forceps than pethidine alone ($P<0.01$). Those receiving an extradural had the same duration of first and second stages. Mothers receiving an extradural rated their quality of analgesia higher than those receiving pethidine alone ($P<0\ 001$).

Our results suggested that a "low-dose" extradural analgesic technique did not confer any advantage over pethidine in terms of avoiding instrumental delivery or Caesarean section, even when labour is actively managed.

Effects of nalbuphine, pentazocine and U50488H on gastric emptying and gastrointestinal transit in the rat

T. Asai, W. W. Mapleson and I. Power
Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff, and Department of Anaesthesia and Pain Management, University of Sydney, RNSH, St. Leonards, Australia

Morphine markedly inhibited both gastric emptying and gastrointestinal transit to a similar degree in the rat.[1] We studied the effect of mixed agonist–antagonist opioids (nalbuphine and pentazocine) and a kappa opioid agonist (U50488H) on gastric emptying and gastrointestinal transit, and their interactions with morphine.

In each group of five to eight male Wistar rats, nalbuphine (0.01–30 mg kg^{-1}), pentazocine (1–30 mg kg^{-1}), U50488H (1–100 mg kg^{-1}) or saline was injected i.p. at 0 min. Another four groups of rats received morphine 13.4 mg kg^{-1} (ED75) and one of the following substance, all at 1.0 mg kg^{-1}: saline, nalbuphine, pentazocine or U50488H. Radiolabelled saline 1 ml was infused into the stomach at 30 min; and at 1 h the animal was killed, the gastrointestinal tract was removed and the small intestine was divided into 10 equal segments. The radioactivity in the stomach and in each segment of the intestine was counted; gastric emptying and gastrointestinal transit were calculated.[1] Data for morphine were from a previous study.[1] The Mann–Whitney *U* test was used for comparison of substances or combinations of substances. Slopes for dose-response curves were determined using logistic regression of inhibition, with respect to saline, of gastric emptying and of geometric centre on log-dose.

Nalbuphine significantly, but only weakly, delayed gastric emptying ($P<0.0005$) and gastrointestinal transit ($P<0.01$). Pentazocine markedly inhibited both, whereas U50488H did not significantly inhibit either. The slopes of the dose-response curves for nalbuphine, but not for pentazocine, on both gastric emptying and gastrointestinal transit were significantly less steep than those for morphine (table 2). Nalbuphine significantly antagonized the inhibitory effect of morphine on gastric emptying ($P=0.005$) and gastrointestinal transit ($P=0.02$), whereas neither pentazocine nor U50488H significantly did so.

In the rat, nalbuphine, which only weakly inhibited gastric emptying and gastrointestinal transit, antagonized the inhibitory effect of morphine, whereas pentazocine which inhibited both, and U50488H which did not significantly alter either, did not alter the effect of morphine.

Propofol induction characteristics after fentanyl or midazolam and fentanyl

L. M. Collins*, C. M. Cooney and G. Fitzpatrick
Department of Anaesthesia, Adelaide and Meath Hospital, Dublin 8, Ireland

In a randomized-controlled double-blinded study, we examined the effects of pretreatment with fentanyl or midazolam and fentanyl on induction of anaesthesia with propofol.

Seventy-five ASA I day-surgery patients were allocated randomly to receive either 0.9% saline (group C), fentanyl 1 μg kg^{-1} (group F), or midazolam 0.03 mg kg^{-1} and fentanyl 1 μg kg^{-1} (group MF) 3 min before induction with a sleep dose of propofol. Anaesthesia was maintained with 40% oxygen in nitrous oxide and 3% sevoflurane for 3 min before insertion of a laryngeal mask. Heart rate (HR), mean arterial pressure (MAP) and oxygen saturation (Sp_{O_2}) were recorded at baseline and at 1-min intervals throughout. Pain on injection of propofol and involuntary movements were assessed by a blinded observer. Data were analysed using chi-square test, ANOVA and Student's *t* test as appropriate. Results are presented as mean (SD).

Age, weight, sex and baseline HR, MAP and Sp_{O_2} were similar between groups. In group F and group MF, the dose of propofol was significantly lower than control (table 3). The incidence of pain on injection was significantly lower in group MF and the incidence of involuntary movements was significantly lower in both F and MF groups.

In group MF, Sp_{O_2} decreased from a mean baseline value of 98.2 (1.1)% to 93.76 (3.1)% at 3 min ($p<0.05$). There was no change in Sp_{O_2} in groups F or C. After induction, there was a fall in HR in group F [14 (9.2) beat min^{-1} after 3 min, $P<0.01$] and group MF [8.7 (7.8) beat min^{-1} after 3 min, $P<0.05$]. MAP decreased in group MF before induction [8 (8.5) mm Hg]. After induction, MAP decreased similarly in all groups [group C: 18.3 (14.2) mm Hg; group F: 22.5 (11.5) mm Hg; group MF: 17.2 (10.7) mm Hg].

These findings suggested that fentanyl reduced the induction dose of propofol and lowered the incidence of involuntary movements. Midazolam further reduced propofol requirement,

Table 3 Propofol dose [mean (SD)] and incidence of pain on injection and involuntary movements in the three groups. *$P<0.05$, **$P<0.01$, †$P<0.01$ of fentanyl alone

	Control (*n*=25)	Fentanyl (*n*=25)	Midazolam/ fentanyl (*n*=25)
Propofol dose (mg $kg^{-1)}$	2.76 (0.46)	2.46 (0.42)*	1.99 (0.4)**†
Pain on injection (*n*)	12	10	4*
Movements (*n*)	15	5**	3**

decreased the incidence of pain on injection and in low doses augmented the respiratory depressant effects of fentanyl.

Local anaesthetic agents inhibit [^{3}H] noradrenaline uptake into SH-SY5Y human neuroblastoma cells

P. I. Joyce*, R. Atcheson and D. G. Lambert
University Department of Anaesthesia, Leicester Royal Infirmary, Leicester LE1 5WW

Complex regional pain syndrome type-1 (or reflex sympathetic dystrophy) may occur via sympathetic hyperactivity and is often treated by producing a "chemical" sympathectomy using guanethidine.[1] Guanethidine is taken up via the neuronal catecholamine uptake transporter, uptake-1 [2] and a local anaesthetic is co-administered to reduce the discomfort of the injection. The efficacy of this treatment has been questioned.[3] We hypothesized that the local anaesthetic agent may be inhibiting uptake-1 and hence the uptake of guanethidine. In this study we have examined the effects of a range of local anaesthetic agents on [^{3}H] noradrenaline ([^{3}H]NA) uptake into SH-SY5Y cells that express uptake-1.

SH-SY5Y cells were preincubated in 0.5 ml volumes of Krebs-HEPES buffer, pH7.4 for 15 min in the absence and presence of lignocaine (3 μmol litre^{-1}–10 mmol litre^{-1}), prilocaine, bupivacaine, procaine and dibucaine (10 mmol litre^{-1}). [^{3}H]NA/unlabelled NA (approximately 10–1000 nmol litre^{-1}) was added and the reaction continued for a further 5 min. Reactions were terminated by rapid vacuum filtration. Non-specific uptake was defined in the presence of 10 μmol litre^{-1} imipramine. Data are mean (SEM).

Lignocaine produced a dose-dependent inhibition of [^{3}H]NA uptake with a pIC$_{50}$ of 2.97 (0.01) (1.07 mmol litre^{-1}). Lignocaine (10 mmol litre^{-1}) reduced the maximum velocity of uptake (V_{max}) without affecting the K_m (Michaelis–Menten constant equivalent to half of the maximum velocity) consistent with non-competitive inhibition. (Table 4). Prilocaine, bupivacaine, procaine and dibucaine at 10 mmol litre^{-1} produced >95% inhibition of uptake.

Table 4 Effect of 10 mmol litre^{-1} lignocaine on the K_m and V_{max} for [^{3}H]NA uptake into SH- SY5Y cells. Values were obtained using a double-reciprocal plot of 1/v against 1/[S]

	Number	Control	+Lignocaine	*P*
K_m (μmol litre^{-1})	6	0.70 (0.17)	0.53 (0.11)	>0 05
V_{max} (pmol mm^{-1} mg^{-1} protein)	6	6.61 (1.56)	2.71 (0.49)	<0.05

In this study we have demonstrated that a range of local anaesthetic agents inhibited the uptake of [^{3}H]NA and would therefore be expected to inhibit the uptake of guanethidine when co-administered. Based on a simple bench study in volunteers of varying body size we estimated that 0.5% lignocaine (18.5 mmol litre^{-1}) when injected into an arm would be diluted approximately 17-fold. Assuming homogenous distribution this would yield an "in the arm" concentration of around 1 mmol litre^{-1}, the IC$_{50}$ reported here.

Comparison of two steady state-auditory-evoked response methods for assessing depth of anaesthesia in routine clinical practice

M. L. Swart,* J. J. W. M. Stevens,* J. Risdall* and J. G. Jones
University Department of Anaesthesia, Addenbrooke's Hospital, Cambridge CB2 2QQ

The transient and the steady state auditory-evoked response (AER) both reflect changes in depth of anaesthesia but a high proportion of transient AER data has to be rejected (19 of 35 patients) [1] in awake subjects. We examined the effects of general anaesthesia on two steady state AER methods in 18 patients scheduled for gynaecological or general surgery before and during general anaesthesia. The steady state AER was measured as described previously.[2] In addition to measurements of the coherent frequency (CF) we examined the effect of the auditory stimulating frequency on the power in the first harmonic of the EEG after signal averaging and Fourier transformation. We had previously shown that the steady state AER threshold for loss of consciousness was 27 Hz.[3] Of the 42 measurements of CF obtained before anaesthesia, six decreased to below the 27 Hz threshold (Fig. 3A). However if the mean value for CF was derived for each patient then only one patient had a value below 27 Hz. The power in the first harmonic decreased with increasing auditory stimulating frequency and in the awake subjects the threshold frequency for insignificant harmonic power (FIHP) was at a stimulating frequency greater than 40 Hz . There was only one data point (17 Hz) below 40 Hz (Fig. 3A). During anaesthesia

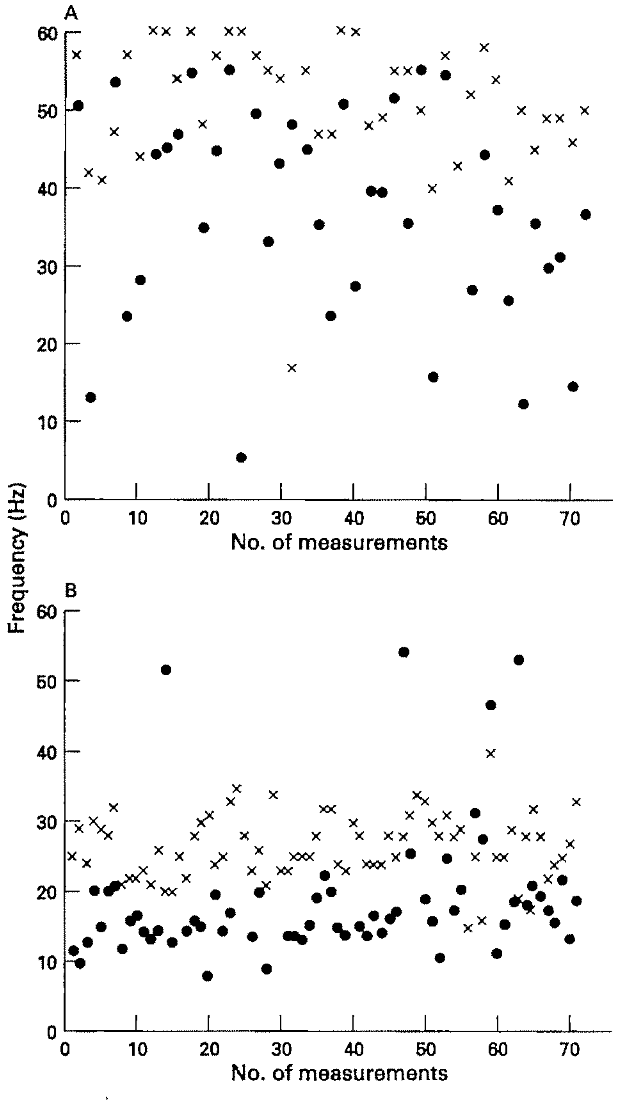

Figure 3 (A) Awake CF (●) FIHP (X). (B) Anaesthetized CF (●) FIHP (X).

(Fig. 3B) there were 71 data points for CF, nine occurring above the 27 Hz threshold. Again when the mean value for each subject was calculated four subjects were above 27 Hz. In the case of FIHP during anaesthesia all but one of the data points were below 33 Hz.

In conclusion, both steady state methods discriminated between the awake and anaesthetized state but the FIHP was a more reliable index than CF.

Use of microalbuminuria as an indicator for the development of sepsis and multiple system organ failure

K. L. MACKINNON[*], Z. MOLNAR[*,†], I. D. WATSON[*], E. SHEARER[†] AND D. LOWE[*,‡]
Department of Clinical Chemistry, [†]Intensive Care Unit, [‡]Clinical Audit Department, Fazakerley Hospital, Liverpool L9 7AL

Mortality in the Intensive Care Unit (ICU) is approximately 30%, half of whom die of sepsis and multiple system organ failure (MSOF).[1] Microalbuminuria has been shown to be a non-specific but sensitive marker of systemic inflammation with a more rapid onset than other common inflammatory markers.[2] We investigated the use of microalbuminuria as an indicator of the development of sepsis and MSOF and compared this with other acute phase markers (C-reactive protein and erythrocyte sedimentation rate) over three days.

Fifty critically ill patients in the ICU were recruited to the study after informed agreement from relatives. Blood samples were collected upon admission and daily for up to three days for the determination of C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) by immunoturbidimetry[3] and the Westergren technique[4] respectively. Urine samples were collected every 6 h for 18 h and the microalbumin:creatinine ratio determined by immunoturbidimetry and Jaffé reaction.[5] To assess the progress of organ dysfunction, multiple organ dysfunction scores (MODS) were obtained daily up to a maximum of 10 days.[6] For statistical analysis, Mann–Whitney and chi-square tests were used as appropriate.

Outcome was assessed according to patient survival (survivors, n=36;non-survivors, n=14). ESR and CRP values obtained throughout the study did not show any association with outcome in either group. Microalbumin:creatinine ratios (reference range <3.5 mg:mmol) obtained within 6–12 h of admission were significantly different (survivors:median (m)=3.3, interquartile range (r)=1–14;non-survivors:m=22, r=3–54;p<0.01). Microalbuminuria concentrations were in concordance with the MODS on day 1 (p<0.002).

We concluded that micoralbuminuria measurements can be used to identify high-risk patients, the earlier identification of these patients means that they can be targeted more accurately with more aggressive clinical intervention.

N-acetylcysteine in multisystem organ failure

Z. MOLNAR[*], E. SHEARER AND D. LOWE[*,‡]
Intensive Care Unit; [‡]Clinical Audit Department; Fazakerley Hospital, Liverpool

Multisystem organ failure (MSOF) remains the biggest challenge in intensive care, and carries a high mortality. The aim of this study was to investigate the effects of *N*-acetylcysteine (NAC), a free-radical scavenger, on mortality and the development of MSOF, when given as a prophylactic treatment to critically ill patients.

After obtaining ethics committee approval, every critically ill patient admitted to our intensive care unit over a 12-month period was entered to the study and a written informed agreement from their relatives was obtained. Those, who had chronic organ insufficiency according to the APACHE II guidelines, and those with isolated head injury or drug overdose were excluded from this randomized, double-blinded, placebo-controlled trial. Patients received either NAC (150 mg kg^{-1} bolus followed by 12 mg kg^{-1} 24 h^{-1}) or the equal volume of placebo (30 ml h^{-1} of 5% dextrose) for a minimum of three up to a maximum of five days. To assess the effects of the treatment on organ function, a multiple organ dysfunction score (MODS) was obtained daily up to a maximum of 10 days.[1] For statistical analysis Mann–Whitney and chi-square tests were used as appropriate.

Of the 86 patients studied 41 received NAC and 45 were given placebo. Age (NAC: median (m)=62, interquartile range (r)=41–69; control: m=63, r=45–73) APACHE II scores (NAC: m=22, r=16–29; control: m=22, r =16–28) and MODS (NAC: m=5, r=4–8; control: m=6, r=4–7) were similar in both groups on admission. Outcome was assessed on leaving the hospital. Mortality rate was 39% in the NAC treated patients, and 29% in the control group but the difference did not achieve statistical significance (P=0.32; 95% CI for mortality differences =−10 to 30%). The progress of the MSOF showed a similar pattern in both groups as indicated by the MODS on day 3 (NAC: m=6, r=3.5–8; control: m=5, r=4–7), and on the final day of assessment (NAC: m=5, r=3–10; control: m=4, r=2–7.5). Regarding the effect of NAC on the cardiovascular, respiratory, renal, liver and haematological systems the changes in the individual organ dysfunction scores were compared using the MODS system, but no statistically significant differences were found.

The role of antioxidants in the treatment of critical illness is unclear. Our prospective, controlled study on 86 patients showed, that NAC treatment at the given dose had no positive effect on outcome, did not improve organ function or the progress of MSOF as indicated by the MODS system.

Midazolam and propofol affect interleukin-8 release from human neutrophils at the post-translational level

H. F. GALLEY AND N. R. WEBSTER
Academic Unit of Anaesthesia and Intensive Care, University of Aberdeen, AB25 2ZD

Interleukin-8 (IL-8) is a potent neutrophil chemotactic and activating factor produced by many different cells, including neutrophils themselves, in response to pro-inflammatory stimuli, via G-protein coupled signal transduction pathways. Both propofol and midazolam have been shown to suppress neutrophil respiratory burst, polarization and chemotaxis.

We have shown recently that the i.v. anaesthetic/sedative agents, propofol and midazolam, suppress the extracellular accumulation of IL-8 from lipopolysaccharide (LPS)-stimulated human neutrophils.[1] Northern analysis with molecular imaging also revealed increased IL-8 mRNA concentrations in the presence of both midazolam and propofol, indicating that transcription of IL-8 mRNA is unaffected. However, the effect on translational processing was unknown. We therefore determined the *in vitro* effect of propofol and midazolam on intracellular IL-8 in isolated human neutrophils. Polymorphonuclear leucocytes were isolated using a single density gradient system, and were incubated with 2 μg ml^{-1} LPS in the presence of propofol or midazolam (1–20 μmol litre^{-1}), or appropriate solvent blanks for 20 h. Interleukin-8 was measured in both supernatants and cell lysates using enzyme immunoassay. Cell protein content was measured using a modified Lowry technique.

As previously, extracellular IL-8 accumulation was decreased dose-dependently by both midazolam (P=0.025) and propofol (P=0.028, Kruskal–Wallis ANOVA). Intracellular IL-8 concentrations increased on exposure to LPS (P=0.05 and P=0.028 for midazolam and propofol respectively, Mann–Whitney U test) and remained increased in the presence of both anaesthetics (fig. 4). These data strongly suggested that the anaesthetic agents exerted their effects at a post-translational level via modulation of transport or secretion of the IL-8 protein from the cell.

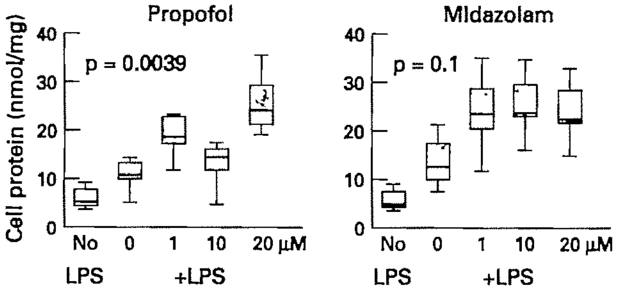

Figure 4 Effect of anaesthetics on intracellular IL-8 concentration in LPS stimulated human neutrophils. Box and whisker plots show median, 25th and 75th percentiles and ranges. *P* values refer to Kruskal–Wallis ANOVA. (n=6–8).

Effects of a single dose of etomidate on adreno-cortical function in the critically ill

A. R. ABSALOM*, D. R. PLEDGER* AND A. KONG*
Department of Anaesthesia, Ipswich Hospital, Ipswich, Suffolk IP1 5PD

Many anaesthetists still use etomidate for induction of anaesthesia in the critically ill, judging that the benefits of cardiovascular stability outweigh the risks of adrenal suppression. The adrenal effects of single doses have been investigated in healthy patients,[1 2] but not in the critically ill. In this study we compared adrenocortical function after induction of anaesthesia with etomidate or thiopentone in critically ill patients.

The study was approved by the local ethics committee. Thirty-five critically ill adults who needed a general anaesthetic were studied. To be included they had to be ASA grade III or worse, and be considered to be critically ill and requiring admission to the intensive care unit. Exclusion criteria were: known adrenal impairment, allergy to relevant drugs and a history of corticosteroid supplementation in the previous six months. Patients were allocated randomly to receive either etomidate (17 patients) or thiopentone (18 patients) for induction. Before induction blood was taken for a baseline cortisol assay. Twenty-four hours later adreno-cortical function was assessed by performing a short synacthen test—an increase in the cortisol concentration of 200 nmol litre^{-1} or more 30 min after injection of synacthen was regarded as a normal response.

There were no statistically significant differences between the groups in terms of age, sex, APACHE II score and baseline and 24-h (pre-synacthen) cortisol concentrations. Patients anaesthetized with etomidate were more likely (P<0.001, Fisher's exact test) to have an impaired response to synacthen (table 5). The mean (SEM) response in the etomidate group was an increase of 97 (27) nmol litre^{-1}, whereas in the thiopentone group the mean (SEM) increase was 237 (25) nmol litre^{-1}; this difference is highly significant (P<0.001, Wilcoxon rank sum test).

In critically ill patients a single dose of etomidate was associated with at least 24 h of adreno-cortical suppression.

Table 5 Results of short synacthen tests (SST)

Agent	Abnormal SST	Normal SST	Total
Thiopentone	5	12	17
Etomidate	15	2	17
Total	20	14	34

Lanz tube as alternative for ICU hyperbaric oxygen therapy

Z. MOLNAR* AND P. CHARTERS
NW Emergency Recompression Unit/ Department of Anaesthesia, Aintree Hospitals, Liverpool

Tracheal tubes cuffs during intensive care unit (ICU) hyperbaric oxygen treatments need to resist pressures equivalent to 3ATA. Saline filled or sponge foam cuffs (for example, Bivona) are recommended.[1] The foam cuff requires a good fit in the trachea and overinflation with saline may risk tracheal injury. For high volume, low pressure cuffs, maintenance pressures of 25–30 cm H_2O are desirable.[2] The Lanz tracheal tube was considered worthy of investigation as an alternative.

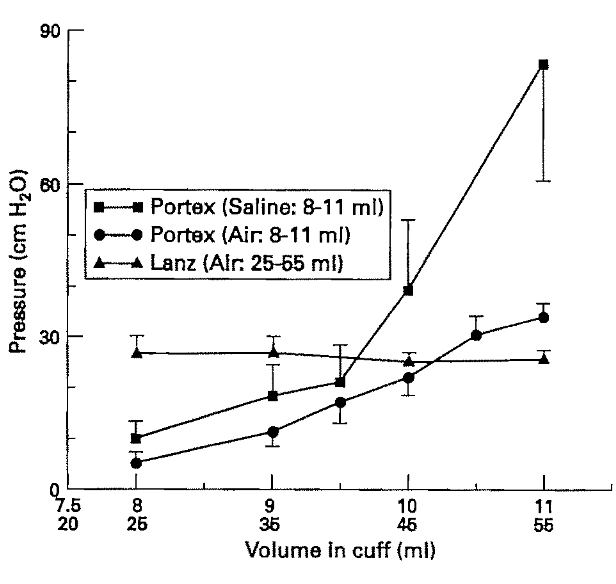

Figure 5 Effect of cuff volume on cuff pressure. (Measured at surface pressure). Four tracheal tubes per study and two model tracheas (i.e. points mean of eight measurements).

Model tracheas 20 mm in diameter with elastic posterior walls were constructed.[3] At normal surface pressure, they were intubated with size 8.0 Portex tubes inflated with either air (as control) or saline in increments, or size 8.0 Lanz tubes inflated with air (fig. 5). Cuff pressures were monitored with a fluid manometer or pressure transducer attached to the valve of the pilot tubes. The Lanz tubes had stopcocks inserted in their valves. Ability to maintain cuff pressure during hyperbaric conditions was then tested. Two Lanz cuffs were inflated with 60 ml of air and in two others 90 ml of air was used after removal of the outer restricting envelope. Cuff pressures were recorded at surface, 6.1, 12.2, 27.4 and 50.3 metres depth.

The Lanz gave steady cuff pressures for cuff volumes 25 to 55 ml. As expected, there was a sudden overpressure in the saline filled cuffs. Under hyperbaric conditions, the Lanz performed as might be expected from Boyle's law. A cuff filled to 60 ml at surface provided steady pressures down to 12.2 metres only. When the inflating balloon was initially inflated to 90 ml, the pressure was lower than for the normal working range. Hysteresis was unimportant.

A Lanz cuff has potential as an alternative to saline filled cuffs. A balloon capacity of 90 ml (with modified valve) should cover normal therapeutic requirements.

Optimal brain tissue oxygenation during hyperventilation in patients with head injuries: measured by a multiparameter sensor

S. GUPTA* [1], M. L. SWART*[1], P. AL-RAWI* [3], P. HUTCHINSON*3, D. K. MENON[1,2] AND A. K. GUPTA [1,2]
Departments of Anaesthesia[1], Neuro Critical Care[2] and Neurosurgery[3], Addenbrooke's Hospital, Hills Road, Cambridge CB2 2QQ

The benefit of hyperventilation as a method for reducing increased intracranial pressure (ICP) was first demonstrated by Lundberg and colleagues in 1959.[1] However, more recently its use has become controversial mainly because of the risk of decreasing cerebral blood flow to the point of ischaemia.[2] Currently, measurement of cerebral oxygenation and metabolism in patients with head injury rely on indirect methods. In this study, we have used a new multiparameter sensor originally designed for continuous intra-arterial blood-gas measurement, to measure the brain tissue oxygen (PTi_{O_2}), carbon dioxide (PTi_{CO_2}), pH and temperature. Our aim was to identify the range of Pa_{CO_2} at which PTi_{O_2} is optimal.

After informed consent from the relatives of the patients, 10 patients presenting with severe head injury were studied. The sensor (Paratrend 7, Diametrix Medical, High Wycombe, U.K.) was inserted through an adapted Camino bolt into the brain tissue on the side of injury. Invasive arterial pressure, intracranial pressure, jugular bulb venous saturation (Sj_{O_2}) and arterial blood-gases were continuously monitored. Initial readings of PTi_{O_2}, PTi_{CO_2} and pH were recorded at a baseline Pa_{CO_2} of 4.5 to 5.0 kPa. The Pa_{CO_2} was then decreased in a stepwise manner to 3.0 kPa. If the Sj_{O_2} decreased to less than 50%, hyperventilation was abandoned.

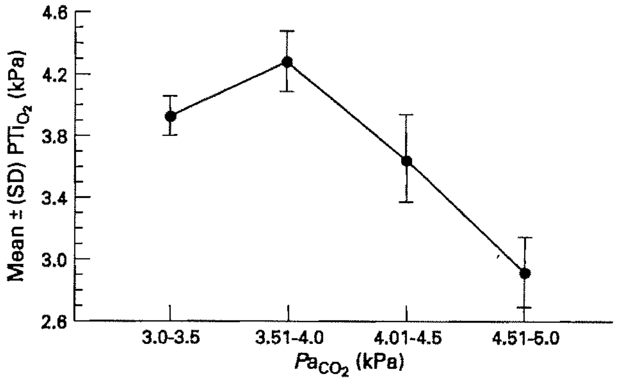

Figure 6 Effect of Pa_{CO_2} on PTi_{O_2}.

There was no significant change in the patient's body and brain temperature, Pa_{O_2} and cerebral perfusion pressure. PTi_{CO_2} decreased with a reduction in Pa_{CO_2}. There was little change in brain pH. When the data are pooled as shown in fig. 6, optimal PTi_{O_2} occurs in the Pa_{CO_2} range of 3.5–4.0 kPa. PTi_{O_2} was significantly higher between 3.5 and 4.0 kPa Pa_{CO_2} compared with baseline ($P<0.0001$).

PTi_{O_2} was optimal between a Pa_{CO_2} of 3.5 and 4.0 kPa. This range is narrower than the previously published range.[3]

Accurate measurement of "true glottic view"

P. GROOM* AND P. CHARTERS
Department of Anaesthesia, Aintree Hospitals, Liverpool

Previous attempts at measuring accurately the view at laryngoscopy described the "true glottic view" in terms of multiple "restricted windows".[1] Two "windows" are especially important: the "reference" window, where the upper incisors are aligned with the posterior glottis and the "vanishing point", the most anterior

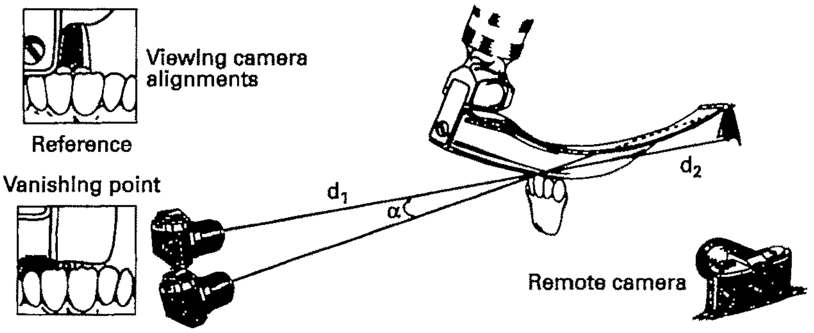

Figure 7 Model simulation.

part of the glottis visible. Restricted window photographs require special considerations because of out of focus magnification phenomena. The introduction of a remote camera eliminated this problem and a novel trigonometric method of indirectly assessing true glottic view evolved as a result. This new method is inherently simpler and refining accuracy is straightforward.

Fixed focus imaging by a single medical photographer was checked for consistency. In a model simulation (fig. 7), if the focusing distance is known, the incisor-glottis distance (d_2) can be estimated by subtracting the camera-incisor distance (d_1).The viewing camera "panning angle" (α) was determined from sequential imaging of the reference and vanishing point alignments by the remote camera. True glottic view is calculated as $2.d_2.(\sin \alpha/2)$. The direct model value for true glottic view is the distance up from the posterior glottis to the intersection with a tangent from the incisor along the blade's lingual surface.

The 95% confidence interval for the fixed focal distance (10 observations) was 57.77 (±0.85) cm. The limits of agreement for the true glottic view were: −0.28 to 0.19 cm. Further refinements are anticipated and an accuracy of ±0.1cm at full glottic exposure should be feasible.

Respiratory complications associated with tracheal intubation and extubation

K. Koga*, T. Asai, C. McBeth* and R. S. Vaughan*
Department of Anaesthetics and Intensive Care Medicine, University Hospital of Wales, Cardiff

Several respiratory complications may occur during tracheal intubation and extubation, but the incidence of these is not clear. Therefore, we studied these incidences.

In a prospective manner, we conducted a survey regarding the incidence of complications associated with tracheal intubation and extubation. The data sheet was designed to obtain the following: the view of the oropharynx (Mallampati score); respiratory complications during induction of anaesthesia; the view of the glottis at laryngoscopy (Cormack and Lehane's score); respiratory complications at tracheal extubation and in the recovery room. Anaesthetists were asked to obtain data during anaesthesia from all patients who underwent elective surgery and in whom the trachea was intubated. Data were not obtained when the patient was transferred to the intensive care unit before tracheal extubation, or when tracheostomy was performed during operation. Nurses were asked to fill in the data sheet for the events in the recovery room. If there were omissions, an investigator contacted the anaesthetist or nurse and rectified the omission.

There were 1200 patients who were subjects for the survey during a 4-month period. We collected data from 1011 patients, but the data from six patients were incomplete. Therefore, data from 1005 patients were used for analysis (collection rate: 83.8%). Respiratory complications occurred in 46 patients (4.6%) during induction of anaesthesia (table 6). Complications occurred immediately after tracheal extubation in 74 patients (7.4%) and in the recovery room in 95 patients (9.5%) (table 6), with a total of one or more incidents after tracheal extubation in 154 of 1005 patients (15.3%).

The incidence of respiratory complications associated with tracheal extubation were comparable to, or even higher than, that during tracheal intubation.

Predicting the moisture-conserving performance of breathing system filters with different anaesthetic breathing systems

A. R. Wilkes* and J. S. Mecklenburgh
Department of Anaesthetics and Intensive Care Medicine, University of Wales College of Medicine, Cardiff CF4 4XN

Breathing system filters (BSF) are recommended for use in anaesthesia to reduce the risk of cross-infection.[1] When placed at the Y-piece, a BSF acts as a heat and moisture exchanger (HME), reducing the moisture loss from the patient. According to the international standard for HME,[2] the moisture-conserving performance is determined by using dry gas on the machine side of the device under test. However, with some anaesthetic breathing systems, the gas in the breathing system (BSG) will be at least partly humidified. This will further reduce the loss of moisture from the patient. The extent of this reduction was investigated by measuring the moisture loss from a patient model.

The patient model "breathed" spontaneously (0.5 L V_T, 20 beats min^{-1}, 1:2 I:E ratio), expiring fully saturated gas at 34°C (moisture content 37.7 mg $litre^{-1}$). Three each of four different BSF were tested. The BSF was connected to the patient model. A T-piece was connected to the machine side of the BSF and humidified air passed through the T-piece at 45 litre min^{-1}, a flow greater than the predicted inspiratory flow. This humidified air represented BSG. Three different humidity levels of BSG were generated (mean (SD) 7.2 (0.2), 12.6 (0.3) and 19.2 (0.3) mg $litre^{-1}$) and the net moisture loss from the patient model was measured gravimetrically over 2 h for each level. The same levels were used for each BSF in increasing order of humidity, after a 1-h stabilization period at the lowest humidity level of BSG.

The measured moisture loss from the four BSFs varied from 1.8 to 14.8 mg $litre^{-1}$ depending on the device and the moisture content. Moisture loss was related to moisture content of the BSG by the equation:

$$l_c = l_o - \frac{c}{31}(l_o - 1)$$

where l_c is the net moisture loss from the patient model (mg $litre^{-1}$), c is the moisture content of the BSG (mg $litre^{-1}$), l_o is the moisture loss when $c=0$.

The mean (SD) difference (predicted−actual) was −0.08 (0.27) mg $litre^{-1}$. l_o is obtained when determining the performance of HME according to ISO 9360. Values of l_o are published in the Medical Devices Agency's series *Evaluation* Values of c for various breathing systems are available.[3] The moisture-conserving performance of BSF can therefore be predicted readily when the BSF is used with different anaesthetic breathing systems.

Table 6 Ranked incidence (percentage and 95% confidence limits [CL]) of specific respiratory complications and total of any one or more complications associated with tracheal intubation and extubation

During induction of anaesthesia		Immediately after extubation		In the recovery room	
Coughing	1.5	Desaturation (<90%)	2.4	Airway obstruction	3.8
Difficult ventilation	1.4	Breath-holding	2.0	Coughing	3.1
Desaturation (<90%)	1.1	Airway obstruction	1.9	Desaturation (<90%)	2.2
Difficult intubation	0.8	Laryngospasm	1.7	Laryngobronchospasm	1.0
Laryngospasm	0.4	Apnoea, hypoventilation	0.9	Apnoea, hypoventilation	0 8
Oesophageal intubation	0.3	Inadequate reversal	0.5	Vomiting	0.7
Gagging	0.1	Vomiting	0.3	Breath-holding	0.3
		Masseter spasm	0.1	Inadequate reversal	0.3
Total of one or more	4.6		7.4		9.5
95% CL	[3.3,5.9]		[5.7,9.0]		[7.6,11.3]

Artificial neural networks for distinguishing disturbed from undisturbed breathing

P. Caleb*, P. K. Sharpe*, A. Black and C. Day
Intelligent Computer Systems Centre, University of the West of England and Department of Anaesthesia, Bristol Royal Infirmary

If breathing pattern, as monitored by respiratory inductance plethysmography, contains information on the likelihood of imminent cessation of spontaneous breathing in patients receiving potent analgesic treatments, any such information is probably contained in periods of quiet breathing rather than in periods of disturbance from talking, coughing, bodily movement, etc. We explored the feasibility of using artificial neural networks [1] for automating the distinction of undisturbed from disturbed breathing in signals of ribcage movement from five patients who had been monitored overnight after various types of surgery. A difficulty is to establish the range of what constitutes undisturbed breathing.

Trial and error identified four useful features of breathing pattern that were extractable from 30-s samples of processed signal (CED 1401, Cambridge Electronic Design Ltd): (i) the number of peaks, (ii) the variability of the inter-peak interval, (iii) the "straightened length" of the signal and (iv) the accumulated absolute difference between adjacent peaks. For an exploration of supervised learning, the features were extracted from 30 segments of breathing from one patient: these had been labelled by eye as "undisturbed". The multivariate normal distribution of the four features was estimated and the set of undisturbed exemplars was expanded five times by bootstraping. A set of 5 multilayer perceptrons (MLPs: Graphical Interface for Multiple Neural Networks package) was trained by error back-propagation to recognize as "disturbed" any segment of breathing pattern whose features were more than 3 SD from the centroid of undisturbed features. Each MLP had four input, two hidden and one output nodes. The set used a majority voting system to classify two fresh sets of pre-labelled exemplars, one from the same patient and another from a different one. The best criterion for discrimination gave 100% sensitivity and 94% specificity on data from the same patient, and 88% sensitivity and 95% specificity on data from the other patient. The tedium, labour and uncertainty in pre-labelling training and test segments curtailed further exploration. As an alternative to pre-labelling each individual segment by eye, we also explored unsupervised learning in a self-organizing map or Kohonen network. Nine hours of signal (three from each of three patients) were used with the SOM-PAK package (University of Helsinki) to train self-organizing maps to recognize clusters of features and map them on to a 7 x 4 hexagonal lattice along with the trajectory of successive segments. The visually recognisable affinities (permutations and combinations of baseline disturbance, regular or irregular, fast or slow) between segments of pattern that mapped to different parts of the lattice were then used to label the map. The map was tested using fresh segments of breathing from the three patients whose patterns had been used in the training and from the two whose patterns had not. The fresh segments appeared to be placed in the appropriate regions of the map.

A combination of SOM and MLP appeared worthy of further study.

Estimation of cardiac output using the Maxima breathing system

***D. M. Miller, *J. Greef and *J. A. Wessels**
Department of Anaesthesiology, Tygerberg Hospital, 7505, South Africa

The Maxima is a new breathing system which is used as a rebreathing system in controlled ventilation with the selective elimination of alveolar gas.[1] Under these conditions, effective

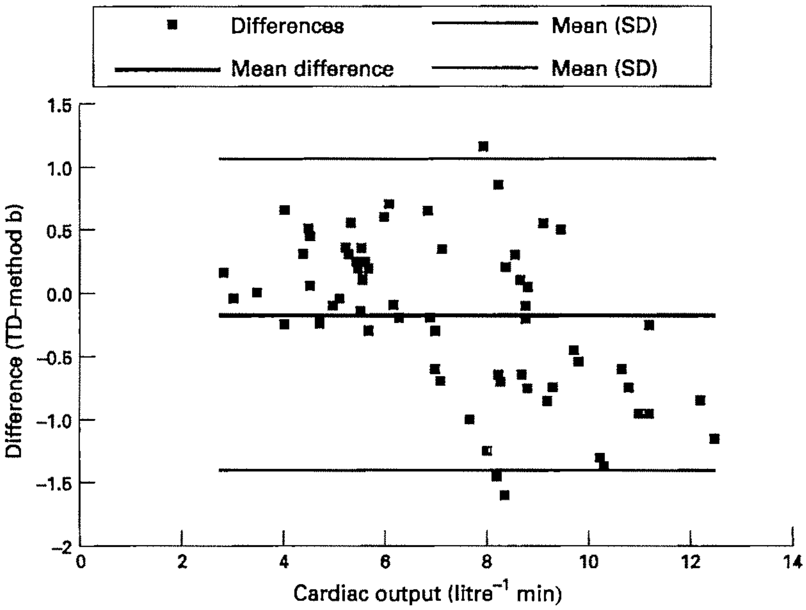

Figure 8 Bland and Altman plot of pulmonary blood flow estimates (two for each subject) according to method (b) against the thermodilution method (TD).

alveolar ventilation is equal to the fresh gas flow ($\dot{V}F$). Without the need for a mixing chamber, "mixed" eliminated carbon dioxide ($F\bar{E}_{CO_2}$) may be measured directly. With steady state conditions, and assuming a respiratory quotient of 1, carbon dioxide production ($\dot{V}_{CO_2}$)$=\dot{V}F\times\bar{E}F_{CO_2}$. The non-direct Fick principle applied to carbon dioxide exchange ($\dot{Q}=\dot{V}_{CO_2}$/pulmonary venous to artery carbon dioxide content difference ($Ca_{CO_2}-C\bar{v}_{CO_2}$) may be modified to $\dot{Q}=\dot{V}F\times F\bar{E}_{CO_2}/(Ca_{CO_2}-C\bar{v}_{CO_2})$. If $\dot{V}F$ in the breathing system is adjusted so that $F\bar{E}_{CO_2}$ is equal to ($Ca_{CO_2}-C\bar{v}_{CO_2}$, then $\dot{Q}=\dot{V}F$. It has been shown that $\dot{Q}=\dot{V}F$, when $\dot{V}F$ is adjusted to achieve an $F<_{CO_2}$ value of approximately 4.1 kPa [equivalent to a ($Ca_{CO_2}-C\bar{v}_{CO_2}$) value of 4.1 ml dl^{-1}].[2] This was demonstrated in a pilot study using nine patients with haemoglobin concentrations (Hb) >10 g dl^{-1}, general anaesthesia and septicaemia with high output in the Intensive Care Unit (ICU).[2] The inaccuracy level was 9%, bias −0.05% and correlation coefficient r=0.94.[2]

This study extended the application within the ICU setting to include a wide variety of conditions all requiring ventilation and haemodynamic monitoring and no limitation was placed on Hb values (mean value=11.5, range 6.2–15.5 g dl^{-1}). Cardiac output was estimated using a thermodilution (TD) technique in 33 patients, all in the ICU except for five who were evaluated during general anaesthesia. Cardiac outputs were estimated using information from (a) $\dot{V}_{CO_2}$ measurements and (b) $\dot{V}_{CO_2}$ and Hb. The results with respective methods (a) and (b) applied to the 33 subjects yielded a correlation with TD measurements—coefficient r=0.9 and 0.91 with a bias of −13% and −4% and inaccuracy of 15% and 14% (fig. 8).

Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents

M. T. CARROLL*, D. LOWRY*, R. K. MIRAKHUR AND K. C. MCCOURT*
Department of Anaesthetics, The Queen's University of Belfast, Belfast BT9 7BL

Cisatracurium is a recently introduced intermediate duration non-depolarizing neuromuscular blocking drug with a potency approximately three to four times that of atracurium.[1] It has also been shown previously that different neuromuscular blocking agents exhibit different degrees of prejunctional effect as shown by different degrees of train-of-four (TOF) fade.[2] In this study we have compared the neuromuscular blocking and prejunctional effects of cisatracurium with other neuromuscular blocking agents.

Ninety adult patients were included in the study with their informed consent but four of these were subsequently excluded because of protocol violations. They were anaesthetized with fentanyl 1–5 μg kg^{-1} and propofol 1.5–2.5 mg kg^{-1}, 66% nitrous oxide in oxygen and a propofol infusion. The ulnar nerve was stimulated at the wrist with supramaximal stimuli of 0.2 ms duration, in a TOF mode at 2 Hz every 12 s and the force of contraction of the adductor pollicis muscle recorded. Patients were allocated randomly to receive cisatracurium 0.05 or 0.1 mg kg^{-1} (Cis 0.05 and Cis 0.1), atracurium 0.5 mg kg^{-1} (Atra), mivacurium 0.15 mg kg^{-1} (Miv), vecuronium 0.08 mg kg^{-1} (Vec) or rocuronium 0.6 mg kg^{-1} (Roc), these being the approximate of one and two×ED$_{95}$ of cisatracurium and two×ED$_{95}$ of other blocking agents. The times to onset and various end-points of spontaneously occurring recovery were recorded. The TOF ratios at approximate heights of T1 of 90, 75, 50 and 25% during onset and recovery of block were calculated. The data were subjected to Kruskal-Wallis and Dunn tests.

Onset of maximum block was slower with both doses of cisatracurium compared with other blocking agents (see table 7). The recovery of block to all the end-points was significantly more rapid after mivacurium. The duration of action of cisatracurium 0.1 mg kg^{-1} was longer compared with equipotent doses of other blocking agents but the differences were not significant in this respect. Significantly greater fade in the TOF was observed with the lower compared with the higher dose of cisatracurium. Otherwise the differences in TOF ratios at various heights of T1 were small. Greater fade was observed during recovery than during the onset of block with all blocking agents Our results showed only small differences in the TOF fade between the equipotent doses of the relaxants.

infants. Accordingly, we evaluated the cardiovascular effects and time-course of action of cisatracurium in infants compared with children.

Twenty-four infants (1–23 months) and 24 children (2–12 years) of ASA class I–II were studied. Premedication consisted of oral or nasal midazolam; anaesthesia was induced and maintained with thiopentone–alfentanil–nitrous oxide–oxygen. Routine monitoring consisted of ECG, non-invasive blood pressure and oxygen saturation. Neuromuscular transmission was monitored using single-twitch stimulation at 10-s intervals (Datex Relaxograph). After stable anaesthesia and calibration of the monitor, cisatracurium 0.15 mg kg^{-1} (3×ED$_{95}$) was administered as a rapid i.v. bolus. Onset and recovery data were analysed by the unpaired *t* test.

Cisatracurium 0.15 mg kg^{-1} produced no significant cardiovascular effects, cutaneous flushing or other untoward reactions. The onset and recovery times are shown in table 8.

Onset times were shorter and recovery times longer in infants compared with children; however, the differences were small and unlikely to be clinically important. We concluded that cisataracurium is a promising alternative to atracurium in paediatric anaesthesia.

Effect of neuromuscular block using vecuronium on oxygen consumption in critically ill adults

P. B. Loan*, M. J. Symington*, R. K. Mirakhur[1], J. R. Johnston, T. J. Trinder* and C. J. Patterson[2]*
Department of Anaesthetics, Royal Victoria Hospital Belfast;
[1]Department of Anaesthetics, Queen's University Belfast;
[2]Department of Epidemiology and Public Health, Queen's University, Belfast

Neuromuscular blocking agents are often used to reduce oxygen consumption ($\dot{V}_{O_2}$-I) in intensive care patients.[1] A previous study showed a beneficial effect, particularly in patients who were moving before paralysis.[2] However, pancuronium, which has significant haemodynamic effects, was used in this study. Also, the one-directional crossover design used cannot detect carryover effects, or distinguish between treatment and period effects. This study was designed to examine any carryover, period or treatment effects of neuromuscular block with vecuronium on oxygen use in sedated critically ill intensive care patients.

Twelve patients were included in the study. All met criteria for the systemic inflammatory response and acute respiratory distress syndromes, and had had pulmonary arterial catheters in place for at least 12 h. Patients were excluded if neuromuscular block was indicated other than for ventilation. Sedation to Ramsay scale grade 5–6 was with morphine (or alfentanil if renal failure was present) and propofol infusions. Ventilation, and sedative, analgesic and cardioactive drug infusions were stable for at least 1 h before the study. Gastric tonometers were in place, and an i.v. infusion of ranitidine 50 mg 4-hourly was administered during the study.

Six patients each were allocated randomly to be paralysed first (PNN) or non-paralysed first (NPP) groups. Group PNN received vecuronium 0.05 mg kg^{-1} followed by an infusion to maintain one to two responses in the train-of-four (TOF). After 40 min, haemodynamic measurements and measurements of arterial and mixed venous oxygen saturations and partial pressures were made, in addition to gastric tonometric pCO$_2$. vO$_2$-I, oxygen delivery (DO$_2$-I) and gastric mucosal pH (pHi) were calculated by standard formulae. Neuromuscular function was allowed to recover spontaneously (TOF ratio >0.9) before two further 40-min periods, without blocking agent. Group NPP underwent three similar 40-min study periods, but in the order non-paralysed, paralysed, paralysed. The data were tested for period and carryover effects before assessing treatment effect using analysis of variance. $P<0.05$ was considered significant.

No carryover or period effects were observed. Vecuronium paralysis had no significant effect on the measured or calculated variables, including DO$_2$-I and vO$_2$-I (table 9). The results suggested no beneficial effect of neuromuscular block on DO$_2$-I, VO$_2$-I and pHi in non-shivering, sedated, critically ill patients.

Functional iron deficiency in orthotopic liver transplantation

A. Davey-Quinn* and M. C. Bellamy
Intensive Care Unit, St. James's University Hospital, Leeds LS9 7TF

Functional iron deficiency (FID) has been described in renal failure, nutritional deficiency, and chronic ill health. An approach to assessment of FID has been proposed by MacDougal.[1] We have used this to quantify FID in patients presenting for liver transplantation, in an attempt to assess its consequences on outcome.

Forty-four consecutive patients undergoing liver transplantation during a 6-month period were studied. We measured preoperative ferritin concentrations, haemoglobin, and FID (proportion of hypochromic red blood cells measured by flow cytometry). Outcome variables included duration of hospital stay, intra-operative blood transfusion, and postoperative day 7, 14 and 21 haemoglobin and FID. Results, expressed as median (range), were analysed by Friedman ANOVA, Mann–Whitney *U* test, and multiple regression analysis.

Median preoperative haemoglobin was 11.0 (8.4–13.9) g dl^{-1}.

Table 9 Main oxygen use parameters with (P) and without (N) paralysis. DO2- I, VO2-I (ml min^{-1} m^{-2}) and pHi. (Mean [SD])

	Group NPP			Group PNN		
	N	P	P	P	N	N
DO2-I	752 (246)	772 (241)	748 (236)	730 (242)	739 (301)	705 (214)
VO2-I	228 (90)	230 (77)	220 (80)	207 (67)	203 (75)	194 (56)
pHi	7.37 (0.13)	7.39 (0.11)	7.42 (0.11)	7.28 (0.15)	7.25 (0.14)	7.26 (0.23)

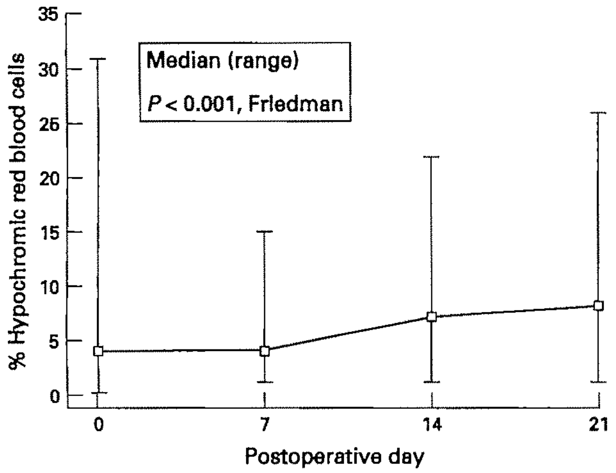

Figure 9 FID trend with time.

Seven patients (16%, 5–27%, 95%CI) had severe FID (>15% hypochromic RBC). Median preoperative hypochromic RBC count was 4 (0–31)%. After operation, this rose to a peak 8 (1–26)% at day 21 (P<0.001) (fig. 9). Median operative blood transfusion was 8 (0–21) units. Preoperative haemoglobin was lower in patients with FID, but this failed to reach statistical significance [10.4 (8.6–12) *vs* 11.1 (8.4–13.9) g dl^{-1}]. Likewise serum ferritin was lower but not significantly so in patients with severe FID [49 (14–1057) *vs* 132 (22–580) ng ml^{-1}], P=ns. Preoperative haemoglobin correlated with intra-operative blood transfusion. Independent predictors of hospital stay were age, FID and preoperative haemoglobin (P=0.05, r=0.44).

Functional iron deficiency is seen in patients presenting for orthotopic liver transplantation. FID could not be detected on the basis of haemoglobin or serum ferritin. Severity of FID correlated with duration of hospital stay. Further work is required to assess the effect of preoperative FID correction on outcome.

Is there a difference in myofilament calcium sensitivity between malignant hyperthermia susceptible and normal skeletal muscle?

S. M. Enright, F. R. Ellis, **P. J. Halsall*** and P. M. Hopkins
Academic Unit of Anaesthesia, St James's University Hospital, Leeds

Differences in response to triggering agents in malignant hyperthermia susceptible (MHS) and normal (MHN) skeletal muscle may be caused by different calcium sensitivities of the contractile apparatus. We wished to compare myofilament calcium sensitivities in MHS and normal, type I and II fibres.

We studied chemically skinned[1] single muscle fibres from six MHS and six MHN patients. Only fibres which generated a maximal tension of ≥80 mg were included. A total of 44 fibres were studied, 18 MHS and 26 MHN. Calcium sensitivity for each fibre was determined by observing isometric tension developed with increasing calcium concentrations (1×10^{-4} mmol litre^{-1} to 1.58×10^{-2} mmol litre^{-1}). Each fibre was then typed using strontium-induced tension[2] into either type I (slow twitch, oxidative) or type II (fast twitch, glycolytic). Dose-response curves for calcium concentration and isometric tension were constructed for the four groups of fibre. From these the calcium threshold concentration associated with half-maximal tension (pCa$_{50}$) and Hill coefficient were derived (table 10).

Table 10 Calcium threshold concentration (mean and 95% CI) associated with half-maximal tension (pCa$_{50}$) and the Hill coefficients for calcium-induced tension in type I and type II single chemically skinned muscle fibres from MHS and MHN individuals

Fibre type	Mean pCa$_{50}$	95% CI	Hill coefficient
MHN I	6.06	6.05–6.07	5.09
MHN II	5.98	5.80–6.01	4.35
MHS I	6.06	5.99–6.12	5.02
MHS II	5.98	5.90–6.03	4.16

We have shown a difference in calcium sensitivity between type I and type II MHN muscle fibres as previously described.[3] We have shown no difference in calcium sensitivity between MHS and MHN muscle. We have found no evidence to suggest that increased calcium sensitivity of the contractile apparatus contributes to the syndrome of MH.

Does the insertion of earplugs affect the bispectral index of the sedated patient in the intensive care unit?

A. J. Pearson, C. J. D. Pomfrett and B. J. Pollard
University Department of Anaesthesia, Manchester Royal Infirmary, Manchester

The bispectral index (BIS) of sedated intensive care unit (ICU) patients has previously been shown to increase during nursing intervention and physiotherapy.[1] Whether this is because of arousal resulting from mechanical stimulation or the effect of noise levels is unclear. Recent work has shown that noise levels in the ICU and in operating rooms consistently remain above 60dB(A), which is classed as the "wake-up" threshold in humans.[2]

ICU sedation aims to provide analgesia, anxiolysis and amnesia in patients, and as such may aid sleep. However in the presence of noise greater than 60dB(A), many sedated patients might find it difficult to sleep. We hypothesized that the combination of ICU sedation and the use of earplugs to reduce the arousal caused by noise might be valuable. This study sought to investigate if the insertion of earplugs into the ears of sedated ICU patients caused any alteration in BIS consistent with more effective sedation and reduced levels of consciousness.

Twelve ICU patients were studied. All patients were receiving fentanyl and midazolam by continuous infusion according to unit policy. BIS was recorded using the Aspect A1000 monitor with "zipprep" electrodes placed in a frontal/mastoid montage. Recordings were made at 5-s intervals and logged directly onto a laptop computer. BIS was recorded on each patient for 1 h. During this hour, patients had either no earplugs in for the first 30 min and earplugs in for the second 30 min or *vice versa*, the order being selected randomly by the toss of a coin. Sound levels were monitored during recording using a simple sound meter. The data were subsequently transferred to a desk top computer and converted into a Microsoft Excel spreadsheet for analysis

In most cases the results did not follow the expected pattern. One patient did demonstrate a significant decrease in BIS after the insertion of the earplugs (P<0.001 Student's t test). Conversely one patient demonstrated a significant increase in BIS after the insertion of earplugs (P< 0.001). Individual data from the other 10 patients were varied with four patients exhibiting a higher overall mean in the earplug group. Overall the data showed no significant difference between the group means (P= 0.28), and there were no significant differences in variance between the groups (P=0.59 ANOVA). Sound levels monitored during EEG recording periods were found to be consistently between 55-70dB(A) with peak increases up to 90-95dB(A) caused by alarms and the telephone ringing.

In this group of patients there was no evidence to suggest that earplugs might reduce the arousal caused by noise in ICU.

Intravenous magnesium does not modify ischaemia–reperfusion syndrome in orthotopic liver transplantation

R. Srinivasa*, A. Morris*, S. M. Enright and M. C. Bellamy
Intensive Care Unit, St James's University Hospital, Leeds LS9 7TF

During human orthotopic liver transplantation (OLT), graft reperfusion may be accompanied by ischaemia–reperfusion syndrome, potentially leading to poor graft function and death. These changes are thought to be mediated in part by changes in cytosolic calcium. Magnesium is a physiological calcium antagonist, and has been used to attenuate ischaemia–reperfusion in cardiac surgery[1] and other models. Animal work suggests protection from hepatic ischaemia–reperfusion injury.[2] We have therefore assessed its effects in OLT.

In a prospective randomized double-blind trial, 40 patients undergoing elective liver transplantation were randomized to receive $MgS0_4$ 10 mmol or placebo during the anhepatic phase at discontinuation of portal bypass (10 min before graft reperfusion). All patients received a standard anaesthetic (alfentanil–air–oxygen–desflurane) and underwent venovenous bypass. Intracellular calcium in monocytes, postoperative liver function tests on days 1, 3 and 5, and mortality were evaluated. Results are given as median (interquartile range). Groups were compared using Mann–Whitney *U* test, and correlations explored by multiple regression.

No patient died during the study. Patient charecteristics in the groups were similar. No variable differed significantly between groups.

As previously described, monocyte intracellular calcium increased after reperfusion in both groups ($P<0.003$). There was no correlation between ischaemic time and outcome. Post-reperfusion $Ca^{2+}i$ correlated with pre-reperfusion $Ca^{2+}i$ ($r=0.9$, $P<0.001$). Both pre- and post-reperfusion $Ca^{2+}i$ correlated with day 3 ALT ($r=0.44$, $P<0.01$ and $r=0.48$, $P<0.005$) but not with promthrombin time or bilirubin (table 11).

Magnesium treatment at this dose did not modify the ischaemia–reperfusion syndrome. Intracellular calcium increased after liver graft reperfusion. Graft function after operation may reflect recipient leucocyte cytosolic calcium.

POSTER PRESENTATIONS

Synergistic effect of fentanyl and midazolam on phrenic nerve activity in rabbits

D. Ma*, S. M. Sapsed-Byrne*, M. K. Chakrabarti and J. G. Whitwam
Department of Anaesthesia, Royal Postgraduate Medical School, Hammersmith Hospital, Du Cane Road, W12 0NN London

A combination of fentanyl and midazolam is often used clinically[1] and while Ben-Shlomo and colleagues reported that midazolam has a synergistic effect with fentanyl on consciousness,[2] as yet the nature of their interaction on ventilation is unknown. This study examined the combined effect of midazolam and fentanyl on phrenic nerve activity (PNA) in rabbits.

Seventeen New Zealand White rabbits were anaesthetized (methohexitone bolus 10–15 mg kg^{-1} and 1% α-chloralose 15–20 mg kg^{-1} i.v.), paralysed (suxamethonium 10 mg i.v. every 20–30 min) and artificially ventilated. pHa, blood-gas tensions and oesophageal temperature were maintained within the normal ranges. The phrenic nerve was exposed in the neck, dissected, desheathed and cut distally, and mounted on electrodes in a mineral oil pool for recording efferent activity. The rabbits were

Table 12 $ED_{25,50,75}$ (95% confidence intervals) for fentanyl (μg kg^{-1} i.v.), midazolam (mg kg^{-1} i.v.) and their interactions on phrenic nerve activity and the ratios of predicted/observed (P/O) $ED_{25,50,75}$ for fentanyl. Predicted doses were calculated from the dose-response curve of fentanyl if the interaction of the two drugs was additive

			Midazolam (0.05 mg kg^{-1} i.v.)+fentanyl		
	Fentanyl	Midazolam	Predicted	Observed	P/O
ED_{25}	1.5 (1.1–1.9)	0.08 (0.04–0.12)	0.9	0.4 (0.3–0.6)	2.3
ED_{50}	3.9 (3.2–4.7)	0.4 (0.3–0.5)	2.4	1.2 (0.5–1.4)	2
ED_{75}	10.1 (8.9–12.6)	2.2 (1.7–3.3)	6.0	3.1 (2.6–3.6)	1.9

divided randomly into three groups. Group 1 ($n=5$), fentanyl was administered in incremental doses of 1, 1, 2, 4 and 8 μg kg^{-1} i.v., each dose over 20 s at 5-min intervals until PNA was abolished. Group II ($n=7$), midazolam was administered in incremental doses of 0.05, 0.05, 0.1, 0.2, 0.4, 0.8, 1.6 and 3.2 mg kg^{-1} i.v., each dose over 20 s at 5-min intervals until maximum depression of phrenic nerve activity was obtained. Group III ($n=5$), a single dose of midazolam 0.05 mg kg^{-1} i.v. was administered, followed 5 min later by fentanyl in incremental doses of 0.5, 0.5, 1, 2 and 4 μg kg^{-1} i.v until the abolition of phrenic nerve activity. At the end of the experiment, it was found that 0.5 mg naloxone and 0.2 mg flumazenil (i.v.) were required to reverse the effect of fentanyl and midazolam respectively.

$ED_{25,50,75}$ (95% confidence intervals) calculated from the dose-response curves are presented in table 12 which demonstrates that the combined effects of midazolam and fentanyl on phrenic nerve activity is synergistic.

These results showed synergistic interaction between the depressant effect of midazolam and fentanyl on phrenic nerve activity and hence potentially on ventilation.

Key words
Phrenic nerve activity. Analgesics, fentanyl. Hypnotics, benzodiazepines, midazolam. Rabbit.

I.v. regional anaesthesia. Comparison of 0.25% prilocaine with or without 5% dextrose

The presence of glucose helps to maintain normal neural conduction.[1] Glucose is usually lacking in solutions used for nerve conduction block except for subarachnoid anaesthesia where its use has been shown to shorten the onset and duration of block.[2] Our aim was to characterize its effects on i.v. regional anaesthesia (IVRA).

Six healthy, fasted male volunteers aged 25–55 years were recruited. Each subject underwent IVRA of the non-dominant arm on two occasions separated by at least two weeks. A 23-gauge cannula was inserted into the dorsum of the hand for the administration of the local anaesthetic. The limb was exsanguinated using an Esmarch bandage and a padded pneumatic tourniquet was inflated to 250 mm Hg. After removal of the bandage, baseline maximum muscle power was measured by the subject squeezing a 1000 ml infusion bag connected to a pressure transducer. Forty ml of local anaesthetic was injected into the arm over 1 min. The solution consisted of 0.25% prilocaine in normal saline or 5% dextrose solution at room temperature. The subject received one solution on the first occasion and the other on the second in a double-blind and randomized fashion. After completion of injection, sensation and motor power were tested at 1-min intervals Sensation was tested over six sites of the forearm in random order, being reported as sharp, touch or absent. At 10 and 20 min the amount of forearm pain was indicated on a visual analogue scale (VAS). Twenty minutes after injection the tourniquet was deflated and testing continued until modalities returned to normal. Monitoring included pulse oximetry and non-invasive blood pressure. Statistical analysis included Student's paired *t* test and one-sample Wilcoxin signed-rank test

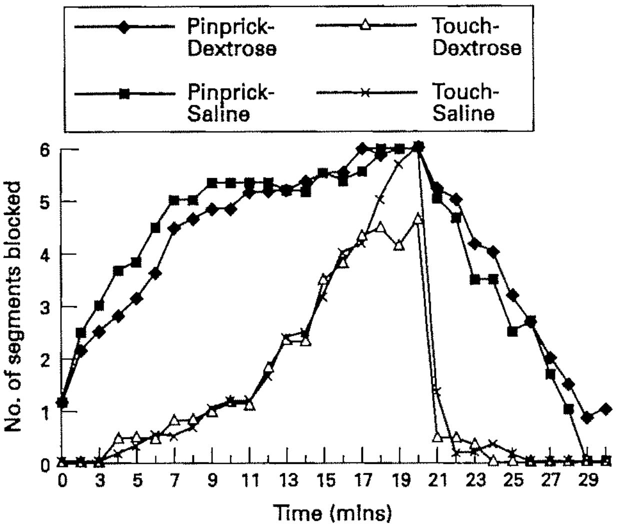

Figure 10 Time *vs* number of segments blocked.

There was no difference in onset or regression of block, or forearm pain scores between the groups. Loss of sharp sensation preceded touch which preceded motor block (fig. 10).

Glucose did not affect nerve conduction during IVRA. This may be because the concentration of prilocaine was too potent or the glucose concentrations achieved at the nerve fibres were inadequate because of redistribution or metabolism.

CORRESPONDENCE

Thorascopic sympathectomy

Sir,—I read with interest the review article by Fredman, Olsfanger and Jedeikin on thorascopic sympathectomy in the treatment of palmer hyperhidrosis.[1] The authors reported on the cardiac complications and noted the two reported cases of intraoperative cardiac arrest,[2] the postulated pathophysiology being that pre-excitation of the myocardium by sympathetic ablation lowers the threshold for ventricular fibrillation.

I wish to report on a 31-yr-old woman undergoing left-sided thorascopic sympathectomy. Induction of anaesthesia was uneventful and a left-sided 37Ch Mallinckroft double-lumen tube was inserted without difficulty. Monitoring included electrocardiogram (ECG) with lead 2 selected, non-invasive arterial pressure (AP), pulse oximetry (Sp_{O_2}), and inspiratory and expiratory gas concentrations. The left lung was collapsed and deflated by clamping the endobronchial tube and opening to air. A size 12 mm trocar was introduced into the chest between the third and fourth ribs in the mid-axillary line under direct vision and carbon dioxide 2 litre insufflated with a pressure limit of 5 mm Hg. Although the lung was deflated, it was difficult to see the T4 ganglia and therefore additional carbon dioxide was insufflated, with the same pressure limit. At this point the patient developed sudden onset of ST segment depression on the ECG. This was not accompanied by changes in P or R waves suggesting that this was not solely the result of a change in the cardiac axis as a result of tension pneumothorax. Arterial pressure decreased from 90/60 to 60/40 mm Hg, with no significant change in heart rate. The surgeon was informed of these changes, and immediate release of carbon dioxide from the hemi-thorax resulted in restoration of a normal ECG within 30 s, and a normal AP after 1 min without the use of vasopressors. As she was now cardiovascularly stable the T2–4 ganglia and sympathetic chain were diathermied. At no time did Sp_{O_2} decrease to less than 96%. The left lung was subsequently fully reinflated and no chest drain was required. Her recovery was uneventful and she was discharged home the next day.

As mentioned in the review, acute hypotension is a recognized complication of capnothorax.[3] In this case, hypotension followed ischaemic changes suggesting that hypotension was attributable, at least in part, to acute reversible myocardial ischaemia. The two reported cases of cardiac arrest occurred during left-sided procedures. It is possible that excess pressure, especially during left-sided procedures, leads to myocardial ischaemia and hence to arrhythmias. Possible mechanisms include: coronary vessel compression as the myocardium is traversed; coronary vessel spasm; reduced coronary flow as a result of torsion of the mediastinum; and reduced coronary flow caused by hypotension. In this case it seems unlikely that hypotension alone was the cause of ischaemic changes as an arterial pressure of 60/40 mm Hg in a healthy, young patient would not usually be expected to be accompanied by ST segment depression. This makes a direct pressure effect seem more likely. Limits on the volume of carbon dioxide were suggested as 1.2 litre,[4] 2.0 litre[5] and 1.0 litre in the review. This case further illustrates the need for extreme caution in the volume and rate of insufflation, but also that myocardial ischaemia, as evident on the ECG, may be the cause of an arrhythmia rather than a lowered threshold for ventricular fibrillation caused by sympathetic ablation.

Sir,—Dr Parry-Jones described a case of acute ST segment depression associated with excessive pneumothorax during thorascopic sympathectomy. Unfortunately, because of the lack of detail of the surgical technique and anaesthetic monitoring, full and accurate analysis of the case presentation is difficult.

In our opinion the pathophysiological events leading to ST depression described in this case were attributable primarily to the inadvertent tension pneumothorax. First, excessive intra-thoracic pressure decreases venous return, stroke volume, cardiac output, aortic root pressure and coronary perfusion pressure. Second, unilateral tension pneumothorax shifts the mediastinum and may result in kinking of the bronchi to the ventilated lung. These events result in hypoxaemia and a decrease in myocardial oxygen supply and may cause acute myocardial ischaemia. Our hypothesis is supported by the fact that all pathological findings disappeared rapidly after the release of the tension pneumothorax. Therefore, we disagree with the conclusion that "hypotension was attributable, at least in part, to acute reversible myocardial ischaemia". As non-invasive arterial pressure monitoring has the disadvantage of being time-cycle dependent, it is possible that arterial pressure during the acute event was much lower than actually captured and displayed. Thus one cannot state that "an arterial pressure of 60/40 mm Hg in a healthy, young patient would not usually be expected to be accompanied by ST segment depression."

When providing anaesthesia for thorascopic sympathectomy the advantages and potential pitfalls of the various techniques should be remembered.[1] When using a tracheal tube, surgical exposure is dependent on continuous insufflation of carbon dioxide into the intrapleural space.[2] To avoid inadvertent tension pneumothorax a pressure-limited, variable flow insufflator is used. In contrast, when using the endobronchial technique, carbon dioxide insufflation is performed to augment lung collapse and protect the lung during insertion of the endoscopic instruments. Thereafter, collapse of the entire lung is accomplished and maintained by the endobronchial tube and carbon dioxide insufflation plays no part in providing surgical exposure. As a result, a pressure-limited, variable flow insufflator is not necessarily required. Thus with the endobronchial technique a tension pneumothorax may occur and extreme caution should be exercised if additional gas is insufflated after lung collapse. Finally, irrespective of the technique used, hypoxaemia is a major concern during thorascopic sympathectomy. It is for this reason that we recommend vigilant Sp_{O_2} monitoring during lung collapse.[3]

Simulated anaesthetic emergencies

Sir,—We congratulate Drs Byrne and Jones for their study of an anaesthesia simulator as a tool for performance evaluation.[1] We have operated a realistic simulation centre for several years[2] and have been involved extensively in the research of anaesthesia simulation as a potential assessment tool.[3 4] We would like to offer the following comments.

The purchase of a realistic simulator represents only a fraction of the cost for the construction of a simulation centre. In fact, the operating costs (mostly salaries for staff) outgrow this initial capital cost within 2 yr.[5] Trying to save money by advocating the initial purchase of a less realistic simulation system may therefore confer only a short-lived benefit and limit the option of expanding simulation of realistic environments in the long term. Furthermore, simplified part-trainers appear to offer a less valuable learning experience compared with realistic simulation environments.[6] In order to substantiate claims that subjects use the same mental models as in real life it is necessary to present data to document that participants indeed "suspend disbelieve" (e.g. rating scales on realism). Otherwise the correlation of findings to clinical events remains speculative.

Physician assessment in anaesthesia to date remains largely a subjective process. Availability of simulators offers the opportunity to expose different individuals to identical scenarios in a high fidelity environment and compare their performance to a "gold standard" reference group. The development of a new assessment tool, however, requires careful evaluation of its reliability and validity[7] in order to define its value compared with accepted evaluation tools.

Drs Byrne and Jones did not measure the reliability of their proposed evaluation tool and given that they did not define the final end-point of a successful intervention, inter-rater reliability may indeed be poor. They neither defined nor validated their time definitions (e.g. the "gold standard" time until the "gold standard" intervention) and did not provide measurements of a reference group (e.g. additional reference group of certified anaesthetists).

It is of interest that the responses to their simulated emergencies appeared to yield such variable results (e.g. some items such as awareness had consistently good responses whereas others such as asystole had mostly poor responses). Statistical tests to measure internal consistency are available (e.g. Crohnbach's alpha) and are helpful in designing tests with internally consistent items. The clinical implications of untreated awareness are very different from untreated asystole and the different responses could be a result of varying degrees of perceived difficulty. In that case, individual scores should be weighted accordingly when combined into the final score for statistical analysis

We believe that simulation has the potential to address some of the shortcomings of traditional evaluation tools. However, practical and clinically relevant scoring systems need to be developed and the reliability of these scoring systems demonstrated. A data base of performance measures of various clinical groups (e.g. the "gold standard" *vs* trainees of various experience) should be generated and demonstrate feasibility and validity of the evaluation tool. Until these studies[8] are complete it is premature to declare that "simulators can be used to assess the ability of anaesthetists to deal with anaesthetic emergencies".

Sir,—We applaud Drs Byrne and Jones for their study[1] of the performance of anaesthetists at different levels of experience in the management of low-fidelity simulations of critical events. The authors have detected the same characteristics of anaesthetists' technical responses as were found over the past 8 yr in previous studies using both hands-on simulators[2–4] and computer-screen simulators.[5] These characteristics are: (i) significant variability in response between individuals and between events; (ii) modest improvement in performance caused by increased anaesthesia experience, especially compared with the most junior personnel; (iii) occurrence of serious, even catastrophic, errors at every level of experience; and (iv) lack of uniform adherence to published guidelines for managing critical events.

These characteristics appear to be reproducible features of anaesthetist performance. That they can be detected with instruments of different fidelity is not surprising (one can see craters on the moon with the naked eye and with a telescope). Furthermore, Byrne and Jones compared their results using the low-fidelity ACCESS simulator[6] with those obtained with early versions of our more hands-on simulator (CASE 1.2/1.3).[7] CASE 1.2/1.3 had greater fidelity than ACCESS because it provided monitoring data via actual clinical monitors, but compared with today's simulators and simulation environments, CASE 1.2/1.3 was itself a low-fidelity simulator.

There were several methodological problems in this study. The presence of the "tutor" acting as an assistant (while operating the simulator) could have altered the results, especially if the tutor was not blinded to the experience level of the subjects. Also, having a tutor to pass equipment is not routine in most anaesthetic environments. Actions were timed to the nearest 30 s, a rather coarse measure given the rapidity with which some diagnostic and therapeutic manoeuvres can be completed (some can even be conducted in parallel), as demonstrated in previous studies in which the simulations were videotaped.[3 4 8–10] Hypervigilance (expecting problems that are not present) and cavalier behaviour (not responding avidly because the patient is not a real human being) are common findings in simulation studies and can affect performance, but these issues were not mentioned by the authors.

We view with scepticism the contention of the authors that "to measure performance...it is not necessary to construct a 'high-fidelity' environment, but merely to provide enough realism to enable those tested to suspend disbelief". First, the authors have not proved that they accurately tested the true *performance* of their subjects, only that they identified characteristics of performance similar to those measured previously. Second, there is no proof that "...subjects used the same mental models as they use in real life and results are therefore valid." No systematic analysis of mental models was conducted. Third, while we agree that suspension of disbelief is necessary when a plastic manikin represents a human being, the authors provided only an anecdote suggesting that one subject suspended disbelief; they provided no data that subjects did so in general. Hence, if the goal was to determine the level of simulator fidelity required to support a given type of performance assessment, this study shed little light on the question. To do so it would be necessary to test the same individuals using comparable scenarios on simulators of differing fidelity.

Moreover, the type of performance assessed in this study, and in previous studies cited, is only a limited portion of clinical skill–technical performance. When simulations are conducted using realistic replications of a clinical environment, complete with actual equipment and supplies, and a full set of clinical personnel such as nurses, surgeons, anaesthetists and technicians, a more complete set of clinical skills can be probed. Over the past 7 yr many investigators have been examining more comprehensive aspects of performance, including crisis management behaviours such as leadership, communication and teamwork.[8 11 12] Techniques to measure these aspects of performance and technical management of complex situations are currently under development.[13–16] We believe that to address the full complexity of clinical management for research studies or for training it is necessary to probe clinicians in settings that challenge the full scope of their abilities. However, as for other part-task trainers and low-fidelity simulators, ACCESS may be useful for investigating and teaching restricted aspects of patient care.

Finally, many simulation centres have expanded their attention beyond anaesthesia to conduct research and training on comprehensive management issues in a variety of medical domains, including combined team performance in the operating room, delivery suite, emergency department and intensive care unit.[17] Such expansion is desirable not only to maximize the benefit of simulation-based training, but also as a way of sharing expenses between multiple user groups. To address the various different clinical arenas, high-fidelity, model-driven multipurpose patient simulators are essential tools in creating a simulation environment that replicates the true complexity of the clinical environment being targeted.

Sir,—We note the comments of Drs Kurrek and Devitt and Drs Gaba and Howard on our article.[1]

Unfortunately, there are some factual errors in the comments of Drs Kurrek and Devitt. First, they assert that it is "necessary to present data to document that participants indeed 'suspend disbelief' (e.g. rating scales about realism)". We have previously published such data.[2] Thus, when we asked subjects who had gained experience on our ACCESS simulator if they agreed with the statement, "The patients' responses were realistic" the median response was 8.5 on a scale of 0 to 10 (0=disagree, 10=agree). Consequently, the realism of the ACCESS simulator was comparable with that of any other anaesthesia simulator.

Second, their statement that the operating costs of a simulator outgrow the initial capital cost within 2 yr is only true for high-fidelity simulation centres. The ACCESS simulator has been designed to be operated by a single tutor and avoids the large operating costs they describe.[3] It can and is being used by single departments of anaesthesia with minimal running costs.

Third, they make the unjustified assertion that "simplified part-trainers appear to offer a less valuable learning experience compared with realistic simulation environments". The claim is refuted by one of their own abstracts. This described subjects' ratings of an unsupported session on a screen-based simulator (ASC) compared with involvement in two simulations on a full-scale simulator, followed by a review of their performance on videotape. As their own abstract states,[4] "The main criticism of the ASC program was the lack of feedback on performance which limited learning". Any educational tool will be rated poorly by subjects if it is used incorrectly.

Drs Gaba and Howard make great claims about complex simulators enabling "realistic replication of a clinical environment complete with .... a full set of clinical personnel such as nurses, surgeons, anaesthetists and technicians". Yet two paragraphs before this statement they objected to our having a "tutor" acting as an assistant because such a person "is not routine in most anaesthetic environments". While this may reflect the poor level of anaesthetic support in the USA, it is certainly not so in the UK where no anaesthetic can be given without the presence of a fully trained operating department assistant (ODA) whose role is to assist and pass equipment.

While the simplicity of the ACCESS system makes it easy to emphasize differences between training on a simple simulator and practising real life anaesthesia, there is no evidence that these differences reduce the educational value of the simulation. To date there have been no published articles on high-fidelity anaesthesia simulators which demon-strate an advantage for such an expensive approach. In fact, where comparisons have been made in aviation,[5] a $30 (£18) plywood mock-up was found to be as effective as a high-fidelity simulator and was no worse than training on a real aircraft. The cost of purchase and operation of a single high-fidelity simulation centre is likely to exceed that of 250 ACCESS simulators, with the latter having the capacity to train vastly larger numbers of anaesthetists. Many of the references quoted are small, limited studies describing equipment or evaluations published only in abstract form. We agree that it is vital to investigate the psychology of dealing with critical incidents and better define what we mean by performance. We also agree with their analogy of not needing high-resolution telescopes to see craters on the moon when simple, cheap glasses may be all that is needed.

Pigs are not humans

Sir,—It was with considerable interest that we read the article of Lentschener and co-workers on the haemodynamic repercussions of pneumoperitoneum in the pig.[1] Although we share the authors' caution concerning extrapolation of animal data to clinical experience in humans, several points in this study which contradict examples in the literature may have resulted in inappropriate conclusions.

Several studies on the haemodynamic effects of pneumoperitoneum have been carried out in the pig[2–4] and have given different results to those of Lentschener and colleagues, being similar to changes observed in humans.[5] Most of the studies quoted by Lentschener and colleagues were carried out in the dog[6 7] which, on the basis of the authors' conclusions on the differences between species, are equally difficult to extrapolate. Moreover, in humans, some studies have not always found the changes usually observed during pneumoperitoneum.[8 9]

Some factors may influence the haemodynamic repercussions of pneumoperitoneum. The most important would appear to be the the state of hydration of the patient; hypervolaemia limits the haemodynamic effects of peritoneal insufflation.[3 6] This could be the case in the study of Lentschener and colleagues where significant vascular filling was used (Ringer's lactate 500 ml h^{-1} for animals weighing approximately 18 kg). The high pulmonary capillary pressure and cardiac flow rate values agree with this hypothesis. Another factor which influences venous return during pneumoperitoneum is the position of the patient[2] and in this study it is not clear in what position the animals were placed. The type of anaesthesia can also have considerable influence on the haemodynamic repercussions observed during pneumoperitoneum[4 6] and it would be interesting to know the exact doses of fentanyl and ketamine used during this study. In addition, we are not sure that domestic pigs weighing 40 kg should be considered as adults.

Without wishing to cast doubt on the results, we feel that experimental and anaesthetic conditions can considerably influence the results of experimentation, which implies that the conclusions should be guarded, especially when they contradict those of most of the literature.

Sir,—Thank you for the opportunity to reply to Drs Bazin and Schoeffler. We noted that Bazin and Schoeffler supported our conclusions that: (a) haemodynamic changes recorded when intraperitoneal pressure is increased differ depending on the study and (b) pharmacological or physical potentiating agents may alter haemodynamic changes associated with increased intraperitoneal pressure in humans and in animal models. However, in our opinion, the objections raised by Bazin and Schoeffler are not supported by the articles quoted in their reference list.

With the aim of supporting the fact that haemodynamic changes resulting from increased intraperitoneal pressure in humans may be reproduced reliably in pigs, Bazin and Schoeffler refer to two models (references 2 and 3 of the letter). Indeed, Ho and colleagues (reference 3 of the letter) maintained general anaesthesia throughout their study by continuous i.v. infusion of ketamine. Therefore, the increase in both arterial pressure and systemic vascular resistance may have been related to the direct sympathetic effect of i.v. ketamine.[1] Furthermore, in the investigation conducted by Junghans and colleagues (reference 2 of the letter), general anaesthesia was maintained throughout the study by nitrous oxide exclusively. Nitrous oxide is a weak analgesic which does not produce surgical analgesia. Therefore, pain may have accounted for the increase in arterial pressure. Moreover, in the study of Junghans and colleagues, arterial carbon dioxide tension increased from 4.5±0.1 to 6.4±0.1 kPa when pneumoperitoneum was created. This acute hypercapnia may also explain the increase in arterial pressure and systemic vascular resistance in this study. Finally, Bazin and Schoeffler are the only authors who reported, in an abstract (reference 4 of the letter), that they reliably reproduced haemodynamic changes in pigs resulting from increased intraperitoneal pressure in humans, with no potentiating agent. However, the method was not detailed sufficiently in the short abstract. Therefore, we do not understand how they could produce these haemodynamic changes in pigs when other investigators have failed to do so.

In our investigation, volume expansion may explain the high pulmonary capillary pressure measured in pigs. However, neither the study of Ho and colleagues nor that of Diamant, Benumof and Saidman (references 3 and 6 of the letter) demonstrated suppression of haemodynamic changes associated with increased intraperitoneal pressure by volume expansion in previously euvolaemic animals. Thus, Ho and colleagues studied the effect of pneumoperitoneum on haemodynamics in haemorrhaged pigs, which were compared with euvolaemic animals, with no reference to hypervolaemia. Furthermore, Diamant, Benumof and Saidman studied the effect of hypovolaemia on cardiac function after intraperitoneal pressure was increased to 40 mm Hg. This is higher than the 15 mm Hg of pressure used during laparoscopic surgery.

Bazin and Schoeffler questioned in which position haemodynamic data were recorded in our study. As described in the methods, haemodynamic data were recorded in the horizontal position.

We did not investigate pigs in other positions as we failed to reliably reproduce haemodynamic changes associated with pneumoperitoneum in the supine position.

Bazin and Schoeffler suggested that the way we conducted general anaesthesia may have altered our findings. First, general anaesthesia is induced in pigs with i.m. ketamine in most investigations. I.m. ketamine was used for induction of general anaesthesia in most studies mentioned in Bazin and Schoeffler's letter (references 1–4, 7, 8). Ketamine stimulates the sympathetic system and is likely to cause increases in arterial pressure and systemic vascular resistance.[1] As increases in arterial pressure and systemic vascular resistance were expected in our investigation but did not occur, we conclude that ketamine had no effect. The method of anaesthesia was discussed extensively in our article and in our opinion we definitively ruled out possible pharmacological contamination of our model.

Obstruction of the lumen of a plastic 15-mm connector inserted into a cut paediatric tube—Is it possible to avoid this damage?

Sir,—We read with interest the report of a critical incident by Gupta and Harry[1] illustrating the risks of inserting a connector after cutting a paediatric tube. This problem, encountered with Portex 8.5-mm paediatric tracheal tube connectors, was described originally by May and Kirton in 1993.[2]

At about the same time, we had a similar experience with a 3.5-mm internal diameter (id) tracheal tube (TT) produced by Rusch, Germany. Immediately before anaesthesia was induced in an 8-month-old boy with an incarcerated inguinal hernia, the 3.5-mm id TT had been cut to 12 cm. While trying to insert the plastic 15-mm connector into the proximal end of the cut tube, I noted that the connector buckled inwards, occluding its lumen. The damaged connector was removed and a fresh connector, originally packed with a 3.5-mm id TT, was inserted into the cut tube without damage. Anaesthesia was uneventful.

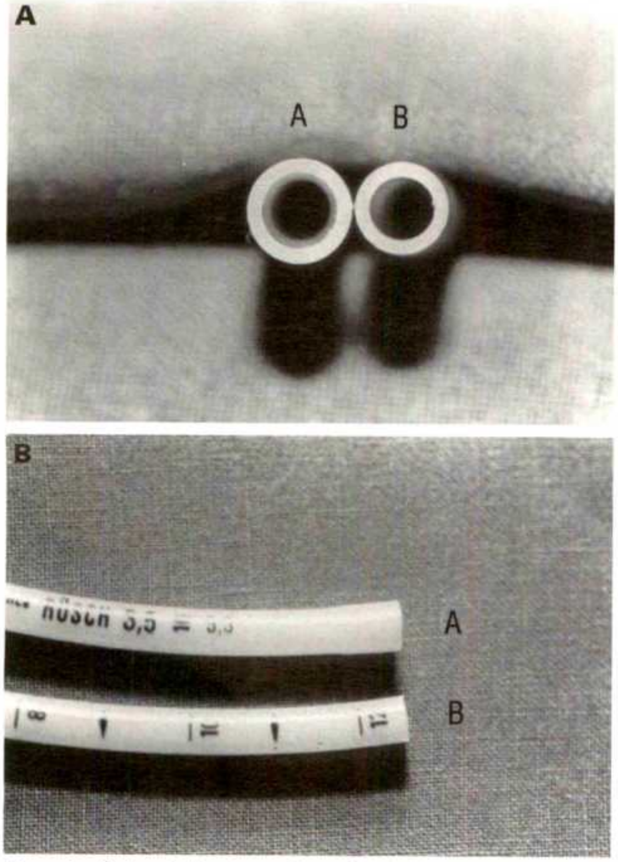

Figure 1 End and side views of an original (A) and manually cut (B) paediatric tracheal tube. Note the different internal diameters.

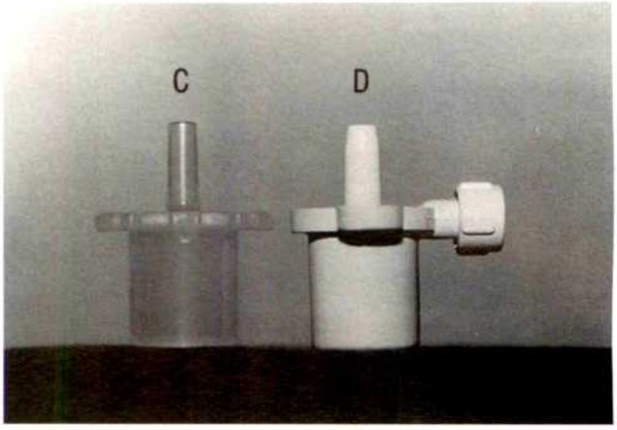

Figure 2 C=Plastic 15-mm connector with a vulnerable tube section provided with a commercially available paediatric 3.5-mm id tracheal tube. D=Special paediatric airway adapter, 3.5 mm id, with a resistant tube section and integral luerlock port.

Subsequent careful inspection of pre-packed paediatric tubes (Rusch, Waiblingen, Germany; Portex Ltd, Hythe, England; Mallinckrodt Medical UK Ltd) showed that: (1) the proximal end of all commercially available paediatric tubes is pre-widened by the manufacturer (e.g. 6–8 mm of a 3.5-mm id TT is pre-widened to approximately 4.5 mm id) (fig. 1); and (2) the tube section of the plastic 15-mm connector is thin and vulnerable (fig. 2).

Thus while it is very easy to insert the original plastic 15-mm connector into the original pre-widened paediatric TT, it requires a very smooth touch to insert the same connector without damage into a tube from which the pre-widened section has been cut away. In our case, the failed attempt to insert the 15-mm connector actually widened the proximal end of the cut tube sufficiently for another connector of equal size to be inserted without any damage.

With respect to our data, we strongly recommend moderately stretching the proximal end of cut tubes crosswise at 9 and 12 o'clock with, for example, an artery forceps or a similar instrument, to avoid damage to the plastic 15-mm connector while it is being inserted into the cut tube. To test the reliability of such self-widened cut tubes into which connectors had been inserted as described, we placed several under water, increased the pressure within them and found that the tubes were always airtight. The elasticity of the tube and the conical shape of the tube section of the connector both work to advantage here. Our method has worked without flaws in all subsequent operating room applications.

Another possibility of avoiding the critical incident described by Gupta and Harry[1] is to use a commercially available special paediatric airway adapter (available from 2.5–5.0 mm id; Ohmeda, Madison WI, USA) if the tube is to be cut. The tube part of this adapter is thick and resistant (see fig. 2) and can be inserted into a cut tube without damage. Nevertheless, here too widening of the cut paediatric tube as described above facilitates insertion of this special paediatric airway adapter. Additionally, this special paediatric airway adapter features minimal dead space and an integral luerlock port for sampling end-tidal values.

BOOK REVIEWS

Positioning in Anesthesia and Surgery, 3rd Edn. J. T. MARTIN AND M. A. WARNER (editors). Published by WB Saunders, Philadelphia. Pp. 345; indexed; illustrated. Price £54.00

This is the third edition of a standard text, the first edition of which appeared almost 20 yr ago; it has undergone considerable revision with contributors being almost exclusively anaesthesiologists with no surgical contributors. The book contains 21 chapters, two forewords and three prefaces and aims to cover a "very important area of anesthesiologic practice" which may frequently be neglected by all except "risk managers, patients and their attorneys". The current interest in risk management should ensure a welcome for the third edition.

The chapters are divided into seven sections: general considerations contains an interesting essay on operating table design and reviews the cardiorespiratory effects of the supine position. The next section comprises four chapters and forms the major portion (25%) of the text, with discussion of dorsal decubitus positions. Most chapters follow a similar pattern, describing the establishment of the position, associated physiological changes and complications. Emphasis on physiology and complications forms the main thrust of the book. The line drawings are excellent, illustrating the anatomy of vulnerable nerve pathways. Lateral and prone positions form the next two single chapter sections followed by "special considerations", comprising a chapter on positioning extremities, mainly an account of the factors and mechanism of peripheral nerve injuries, and head and neck positions. Patient categories contains chapters on lithotripsy, obesity (more an account of potential problems unrelated to position), paediatrics, obstetrics and geriatrics. Consideration of positioning for regional anaesthesia is included. The final section on potential complications is the second largest in the book forming approximately 14% of the text but contains some repetition of parts of previous chapters. The final chapter, medicolegal considerations, while adopting inevitably a transatlantic leaning, offers some sound principles which deserve restatement, including for example the importance of contemporaneous documentation.

This book is very comprehensive and emphasizes again and again the important issues of physiological disturbances and potential harm to patients arising from positioning. Although not an essential purchase for the individual, every library or department should have a copy for access by both surgeons and anaesthetists. Make sure yours has one!

D. Fell

1997 Yearbook of Intensive Care and Emergency Medicine. J.-L. VINCENT (editor). Published by Springer-Verlag, Berlin. Pp. 921; indexed; illustrated. Price DM168.00.

Each year the intensive care community visits Brussels for the annual International Symposium on Intensive Care and Emergency Medicine started 17 yr ago by Jean Louis Vincent. The meeting has a deservedly high reputation with visiting speakers from around the world discussing areas of their particular expertise. When speakers are invited to attend they are also invited to contribute a chapter to the *Yearbook of Intensive Care and Emergency Medicine* which is published to coincide with each meeting. In Brussels, delegates receive a copy as proceedings of the meeting; others have to buy the yearbook but they do get good value.

The *1997 Yearbook of Intensive Care and Emergency Medicine* is the latest volume in the series. Written by contributors to the 1997 Brussels meeting it reflects the current state of intensive care. The book has 19 sections covering a range of subjects from basic mechanisms of sepsis through gut dysfunction to intensive care unit organization and ethics. Each section has several chapters which are up-to-date reviews of subjects close to the hearts of the authors.

The book is full of interesting points but some were compelling for me. There are many theories about the development of sepsis but two chapters present evidence that disordered apoptosis is involved. Apoptosis is the mechanism whereby old or dysfunctional cells die and are phagocytosed. Neutrophils normally undergo apoptosis without releasing cytokines or activating the phagocytes. If a dysfunctional neutrophil does not trigger the programmes for cell death or if it is not phagocytosed at the correct time, it may itself release cytokines or activate the phagocytes to do so. The chapters which present the hypothesis fit together several strands of the pathology of sepsis and SIRS.

No current intensive care book would be complete without mentioning nitric oxide, and this volume devotes a section to the subject. The chapter on the regulatory roles of nitric oxide, such as in microvascular and mucosal permeability, sets a challenge for the future—to understand the role of inducible nitric oxide synthase and why cells should need to produce excess nitric oxide quickly. This challenge is taken up in following chapters on cytokine regulation of inducible nitric oxide synthase and the role of peroxynitrite in the pathogenesis of shock. Nitric oxide binds to haemoglobin and there are two chapters on haemoglobin and sepsis. The way in which nitric oxide binds to haemoglobin depends on its state of oxidation. Oxyhaemoglobin binds nitric oxide to form methaemoglobin, while deoxyhaemoglobin forms nitrosylhaemoglobin. Cell-free haemoglobin has been studied in animals and found to reverse the hypotension of shock. Clinical studies in humans are needed but the few anecdotal reports are encouraging.

Not surprisingly, there are several sections on ventilatory support but the emphasis is on less invasive modes. Reflecting this there is a chapter on ventilation without a tracheal tube during cardiac arrest. This reviews the new recommendation of the European Resuscitation Council to decrease tidal volume to 0.5 litre when ventilating the lungs of a victim of cardiac arrest before intubation. It also recommends strategies to reduce the risk of gastric inflation in this situation Chapters on non-invasive ventilation and modes of ventilation suitable for spontaneously breathing patients whose tracheas are intubated continue this minimalist approach to ventilation. There are also chapters from the invasive extreme, including one on liquid ventilation. These chapters deal with the patient–ventilator relationship and approach ventilatory strategies not only from the ventilator point of view with emphasis on alveolar recruitment but also from the patient point of view with a review of the physiology of ventilation in the prone position.

These are some of the highlights of the book for me. Because different chapters are written independently by different authors, there is some repetition and inevitably the chapter quality is variable. The book does, however, give a worthwhile picture of the present state of intensive care medicine in addition to posing some questions which may be answered in future yearbooks. It provides a useful reminder for those who attend the Brussels meeting (you can never get to all the sessions) and an invaluable update for everyone else.

BRITISH JOURNAL OF ANAESTHESIA

VOLUME 79, No.6 DECEMBER 1997

EDITORIAL I

Inhaled nitric oxide in acute respiratory failure

The use of inhaled nitric oxide in the UK is undoubtedly increasing. The survey by Cuthbertson, Stott and Webster[1] identified 65 adult and paediatric intensive care units (ICU) using nitric oxide, but this may be an underestimate as BOC, Messer and Linde Gas supply medical grade nitric oxide to more than 100 different sites, and the number is increasing. There are approximately 250 ICU in the UK, so this unlicensed therapy is now used by 25–33% of all UK ICU. The survey reported by Cuthbertson, Stott and Webster[1] showed that most units use inhaled nitric oxide to treat acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS), pulmonary hypertension or complications of cardiac surgery.

Some of the centres supplied with nitric oxide and not identified by Cuthbertson, Stott and Webster[1] might be special care baby units. There is now solid evidence to support the use of nitric oxide in hypoxic respiratory failure in neonates, and in persistent pulmonary hypertension of the newborn (PPHN). These conditions overlap somewhat, as acute lung conditions in infants such as meconium aspiration cause pulmonary hypertension, and idiopathic persistent pulmonary hypertension of the newborn causes right to left extrapulmonary shunting and hypoxaemia. In a study published earlier this year,[2] nitric oxide was compared with placebo in a multicentre, randomized, blinded, controlled study. A total of 235 infants were studied. Although there was no difference in mortality, there was a 28% reduction in the number of infants who required extracorporeal membrane oxygenation (ECMO) in the group treated with nitric oxide. In the same edition of the *New England Journal of Medicine*, a randomized, controlled, blinded study of 58 term infants with PPHN showed a 44% reduction in the need for ECMO, but again no difference in mortality.[3]

As neonatal ECMO alone almost certainly reduces mortality in infants with hypoxic respiratory failure,[4] these studies suggest that if oxygenation is supported in these infants, either with ECMO or inhaled nitric oxide, mortality will be lower than in infants receiving neither of these treatments, but that nitric oxide and ECMO are probably equally effective. This is reinforced by the observation that the causes of death of infants dying in the nitric oxide and control groups were similar. However, the advantages of inhaled nitric oxide treatment over ECMO are considerable: it is cheaper, simpler and probably does not need to be confined to specialist centres so avoiding complex inter-hospital transfers. The results of these two studies will probably be sufficient for the FDA to issue a licence for the use of nitric oxide in neonatal hypoxic respiratory failure in the USA. Whether or not inhaled nitric oxide produces less long-term morbidity than ECMO is still under investigation; a 2-yr follow-up of patients from one of these studies is planned, because the long-term effects of inhaled nitric oxide are unknown and ECMO may produce neurological sequelae not apparent at the time of treatment.

The situation in adults is far less clear. Although ECMO can reduce deaths from hypoxic respiratory failure in neonates, the only two large randomized studies of extracorporeal gas exchange in adult severe acute respiratory failure showed no benefit[5 6] which implies that in this group of patients, supporting oxygenation with more than standard treatments may not reduce mortality. Before the neonatal studies were published the effect of nitric oxide on the use of neonatal ECMO was already suspected, because audit data from ECMO centres showed a declining use of this treatment parallelling the increase in the use of inhaled nitric oxide but there are no similar data which might predict the value of nitric oxide in adults. Randomized, controlled studies of the effect of inhaled nitric oxide on mortality from acute respiratory failure have not yet been published. In the USA, a dose-ranging study of nitric oxide in ARDS sponsored by Ohmeda is now complete but the subsequent randomized controlled study is still underway and only interim results are available.[7] Recruitment to this study is slower than expected. The pan-European study of inhaled nitric oxide in ARDS sponsored by AGA (a Swedish gas supply company) has been stopped, because of poor recruitment and technical problems with some of the delivery devices. A multicentre study is also underway in France, but no results are available at present. Thus currently there is no clear demonstration of any improvement in mortality in adults with ARDS treated with nitric oxide.

The use of mortality as an end-point in studies of nitric oxide may not be appropriate because death caused by hypoxaemia or right heart failure is not common in the ICU, even in patients with severe ARDS. ARDS is not a condition that occurs in isolation, it is a pulmonary complication of a primary problem. Patients usually die *from* their primary condition with ARDS, not *from* ARDS, and so using nitric oxide to treat this condition may not have a major impact on mortality. This is analogous to the situation in the studies on neonates, where death caused by hypoxaemia was relatively uncommon because ECMO was available, and so nitric oxide had no effect on mortality. However, unlike the use of ECMO in neonates, in adult studies of inhaled nitric oxide an alternative end-point to mortality is not so obvious. Number of days undergoing ventilation is often used as a secondary outcome measure, but there is no clear pathophysiological reason why nitric oxide should lessen the duration of artificial ventilation and the only published data supporting this is a case report.[8] There is no doubt that nitric oxide improves arterial oxygen tension; in the 30 acute "before and after" studies of inhaled nitric oxide in acute respiratory failure published to date, either Pa_{O_2} increased with inhaled nitric oxide by an average of 11.3 kPa, or the Pa_{O_2}/FI_{O_2} ratio increased by an average of 8.7 kPa. There are no studies which show a decrease in Pa_{O_2}. These studies also showed an average reduction in mean pulmonary artery pressure of 4 mm Hg. However, these physiological changes are of little value unless they lead to reductions in mortality, morbidity or duration of stay in the ICU or hospital.

In addition to the problems outlined above, there are also practical problems of study design which may make it difficult to demonstrate a reduction in mortality in adult patients treated with nitric oxide. As only approximately 65% of patients with ARDS show an appreciable increase in arterial oxygenation on inhaling nitric oxide,[7] any study that is totally blinded must have a large number of "non-responders" in the treatment group, and assuming that any reduction in mortality results from an increase in oxygenation, this dramatically reduces the power of the study to detect a change in mortality. This can be countered by increasing the number of patients studied, or by limiting the study to patients who show a suitable response to a test dose. However, limiting the study to patients who respond makes blinding virtually impossible and nitric oxide would be denied to half of the patients who show a response to a test dose. While this is ethically acceptable, because there is no clear long-term benefit from inhaled nitric oxide, practically it would be difficult to withhold nitric oxide from an individual patient with critical oxygenation who showed a dramatic response, especially in an ICU which already uses nitric oxide.

If the large study in the USA shows a clear reduction in mortality when nitric oxide is used to treat ARDS the drug will probably receive a licence from the FDA for adult use, and the Medicines Control Agency in this country might well follow the FDA's lead. However, if the study shows little or no effect a confusing situation will result. A drug will be in use in a large number of ICU in the UK which cannot be shown to be beneficial in a large study, but which individual clinicians believe can be life-saving in certain circumstances. There may be unavoidable flaws in the design of the study, making the negative result less than clear-cut. The company that supplies most of the drug in the UK (BOC) has elected not to charge for it while it is an investigational compound, and so will be losing money, and the patent protection for the product may not be watertight. In this circumstance they might not wish to fund further expensive large scale studies. However, as nitric oxide is now used widely, it would be difficult to cease to supply it to clinicians who believe it is beneficial. The way forward from this scenario is not clear.

EDITORIAL II

"Ecstasy" and the anaesthetist

The drug commonly known as "Ecstasy" is now an omnipresent part of "youth culture" and scarcely a week passes without its mention in the national press, either directly or indirectly associated with death or injury or in relation to some criminal activity. While its proponents claim that it is relatively safe (it is widely perceived as "safer than alcohol") others point to evidence of potential long-term neuropsychiatric morbidity in addition to its acute dangers.

Management of the acute manifestations of Ecstasy poisoning may often fall to the anaesthetist, both in the emergency room and in the intensive care unit. The chronic effects may not pose such a problem, although the profound "hangover" effects of Ecstasy, often lasting 4–5 days, may have implications for the care of patients undergoing elective surgery within this period.

Ecstasy (3,4-methylenedioxymethamphetamine, MDMA, "E", "XTC", "Adam") resembles chemically a combination of amphetamine and mescaline. Its "sister" drug, 3,4-methylenedioxyethamphetamine (MDEA, "Eve") and metabolite 3,4-methylenedioxyamphetamine ("Ice") have been reported to have similar effects.[1–3] MDMA was first produced in 1914 by Merck and used as an appetite suppressant. It was abandoned but subsequently rediscovered in the 1970s when it was used as an adjunct to psychotherapy (making use of the sense of empathy, energy and euphoria as an aid to communication).[1] The commonly experienced effects of MDMA have been described by Peroutka, Newman and Harris after a survey of 100 regular users on an undergraduate campus. They include empathy (90%) and heightened alertness (50%), but also trismus (75%), tachycardia (72%) and bruxism (65%); 67% reported that the positive effects lessened with regular use, while negative effects increased.[4] A recent study by Curran and Travill examined the hangover effects in regular users and found that while a comparable group of alcohol users had recovered after 1 day, MDMA users experienced marked depression and impaired attentional/working memory task performance some 5 days later.[5] MDMA is known to cause release of 5-hydroxytryptamine (5-HT), one of the neurotransmitters implicated in the control of mood[6]; it has also been shown in primates to result in permanent loss of some serotonergic nerve fibres.[7] This has led to the suggestion that regular MDMA use may predispose to long-term neuropsychiatric morbidity. There have been several case reports of the precipitation of acute psychoses by abuse of MDMA.[8 9]

MDMA first became popular as a drug of abuse in the late 1980s. It was listed as a class A drug in the UK in 1977 and banned in the USA in 1985. The first recorded fatality occurred in the USA[1] but many have since occurred in the UK. It has been suggested that this reflects a difference in the pattern of usage.[2] While in the USA, MDMA had been used in a "party" setting, in the UK it found popularity as a "dance drug". This trend, however, has now occurred in the USA. It is used at "raves" where energetic dancing at close quarters for many hours may facilitate development of hyperpyrexia.

The principal acute danger of MDMA is its association with a gross hyperpyrexial reaction and subsequent rhabdomyolysis, disseminated intravascular coagulation and multiple organ failure (MOF). The thermoregulatory centre in the preoptic area of the hypothalamus is known to respond to 5-HT by increasing body temperature (through vasoconstriction, increased muscle tone and shivering, etc.). 5-HT is also implicated in the hypothalamic response to bacterial pyrogens resulting in a shift in the temperature "set-point" during a febrile episode.[10] MDMA is thought to induce marked hyperpyrexia through central mechanisms involving 5-HT$_2$ receptors. It has been shown that agents blocking 5-HT uptake can prevent the acute release and depletion of 5-HT by MDMA.[6] The syndrome of hyperthermia associated with MDMA bears great similarity to that of severe heat stroke, the neuroleptic–malignant syndrome, the serotonergic syndrome and to malignant hyperthermia. This may reflect the final common pathway associated with the consequences of gross hyperthermia. The apparently idiopathic nature of the full acute response may be explained by the presence of some form of metabolic myopathy, as has been suggested in the context of those individuals prone to heat stroke.[11]

The usual presentation in cases of acute toxicity is of hyperthermia, muscle rigidity, obtunded consciousness and in many cases fitting. There appears to be no relation to dose; it may not be the patient's first exposure and others taking from the same supply may be unaffected. The patient may deteriorate rapidly towards MOF, requiring intensive support of cardiovascular, respiratory and renal systems. Five or more organ-system failure has been described, while some such cases have survived.[12 13] Mortality appears to relate to the extent and duration of hyperthermia; the maximum temperature described for a subsequent survivor was 42 °C.[14] All would agree that rapid cooling measures are essential together with support of failing organ systems. Dantrolene has been used to aid control of hyperpyrexia and is recommended by Guy's Poisons Unit (July 1997: if temperature >40 °C). Some authors have doubted its value partly because it treats effect and not cause. The Heatstroke Centre in Makkah, Saudi Arabia, has reported that dantrolene is of no benefit in the treatment of severe heat stroke.[15] In this experienced unit, they were able to study 52 patients over a 4-day period in a randomized, double-blind, controlled study and found that dantrolene had no effect on the rate of cooling. They are however well practised and have equipment for patient cooling not commonly available in the UK. It must also be remembered that heat stroke is a different entity in which the normal thermoregulatory mechanisms have been overwhelmed. In MDMA reactions the thermoregulatory mechanisms may be abnormal. If one considers the most markedly pyrexial cases detailed in the literature, but exclude those with peak temperatures of 42 °C (only one reported survivor[18]) or more, there is some suggestion that dantrolene may be of benefit. Peak temperatures in the range 41–41.9 °C have been associated with four of four survivors in the dantrolene treated group and two of five in the non-dantrolene treated group.[2,12,13,16–19] If this range is broadened to 40–41.9 °C then there were 10 of 10 survivors who received dantrolene compared with six of 10 who did not.[2,3,17,19–24] It has been noted that rapid control of temperature was produced in cases where dantrolene was used.[14,21] In most centres, where a patient is *in extremis*, requiring intubation, ventilation, transfer to intensive care facilities and invasive monitoring and support, any aid to cooling at this busy time may be of benefit.

Awareness of the danger of hyperthermia among users of MDMA has led to the practice of drinking large volumes of water at "rave" parties to prevent the compounding effect of dehydration. Death after MDMA has also been reported to be a consequence of dilutional hyponatraemia and cerebral oedema caused by excessive water intake. This may also be associated with the inappropriate production of antidiuretic hormone.[25,26] Isolated hepatic failure in the absence of preceding MOF has also been reported. It is unclear if this represents a reaction to a contaminant or possibly an idiosyncratic reaction to the MDMA itself.[27]

MDMA has been implicated as a precipitant to deaths from pre-existing heart disease such as cardiomyopathy and, in common with other drugs of abuse, as a contributing factor to accidents and trauma.[1]

MDMA and the consequences of its use may be with us for some time, and the size of the problem associated with chronic use cannot yet be assessed. The manifestations of acute toxicity will continue to present, and a controlled study of such cases will almost certainly require national coordination if further progress is to be made in their treatment.

CLINICAL INVESTIGATIONS

The intubating laryngeal mask. I: development of a new device for intubation of the trachea

A. I. J. BRAIN, C. VERGHESE, E. V. ADDY AND A. KAPILA

Summary

The standard laryngeal mask airway (LMA) functions both as a ventilatory device and as an aid to blind/fibrescopic-guided tracheal intubation. We describe the radiological and laboratory work used to bioengineer a new laryngeal mask prototype, the intubating laryngeal mask airway (ILMA). The aim was to create a new airway system with better intubation characteristics than the LMA. Other design goals were to eliminate the need for head–neck manipulation and insertion of fingers in the mouth during placement. Development was aided by analysis of magnetic resonance images of the human pharynx and laboratory testing with a variety of tracheal tubes. The principal features of this new system are an anatomically curved, rigid airway tube with an integral guiding handle, an epiglottic elevating bar replacing the mask bars, a guiding ramp built into the floor of the mask aperture and a modified silicone tracheal tube developed for use with the device. (*Br. J. Anaesth.* 1997; **79**: 699–703).

Key words
Equipment, masks anaesthesia. Intubation tracheal. Intubation tracheal, technique.

Tracheal intubation using a laryngoscope inevitably involves distortion of the anatomy in order to bring the glottis into the line of sight. In addition, the tracheal tube (TT) is designed for ease of passage when the anatomy is thus distorted and as a result its curvature does not correspond with the contours of the relaxed anatomy of the upper airway. Because it is not always possible or desirable to distort the anatomy, the difficult airway remains an important cause of mortality and morbidity in anaesthesia[1] in spite of a plethora of intubating aids and difficult airway algorithms.[2] The laryngeal mask airway (LMA) has found a place in this arena[3] but suffers from the disadvantages that its airway tube permits only up to a 6 mm TT and is too long to ensure the cuff of the TT does not come to lie between the vocal cords.[4] Further, the tube is not sufficiently rigid to permit manipulation to bring the mask into alignment with the glottis and cannot be removed easily from the TT when intubation has been accomplished.[5] In addition, the mask aperture bars (MAB) may obstruct passage of the TT. Nevertheless, it has the advantage that ventilation can be maintained whether or not the patient's trachea can be intubated. This advantage seemed sufficiently important to justify modification of the standard device to create a more appropriate intubating tool.

The first modification incorporated a change to the LMA airway tube only and has been described elsewhere.[6] We describe how bioengineering principles were applied to the further development of the intubating laryngeal mask airway (ILMA) using magnetic resonance imaging (MRI) and other laboratory work. The aim of the developmental process was to create a new intubating system with better insertion and intubation characteristics by making the ILMA more compatible with oropharyngeal anatomy and identifying a suitable TT for use with the device.

Methods

THE AIRWAY TUBE

Figure 1 shows how the airway tube has been modified in the new version of the ILMA. The form of the tube was derived from head and neck sagittal magnetic resonance imaging (MRI) views in 50 normal subjects whose heads were held in a neutral position (fig. 2) and differs from that described in an earlier study.[6] Ethics Committee approval was not sought as the images had already been taken for clinical reasons unrelated to the airway; confidentiality was maintained. The convex radius of the curve of the metal tube (41.5 mm) represents a value close to the best fit curve from the concave antero-posterior curves of the palato-pharyngeal arch which were traced from the MRI images. The tube is curved around a minimum arc of 128° corresponding to the approximate alignment of the distal end with the glottic axis measured from the MRI images. The minimum internal diameter (id) of the tube was

chosen to be 13 mm, with a wall thickness of <1 mm. This accepted up to an 8.0 mm id cuffed TT. Wider tube diameters were found to be impossible to curve sufficiently tightly to meet the anatomical requirement using stainless steel and moreover could not be drawn down into the correct dimensions for a standard 15 mm outside diameter (od) connector. Stainless steel was chosen because of its compatibility with silicone, high strength (permitting a good id:od ratio), malleability (low risk of fracturing), ease of sterilization and cleaning, and absence of toxicity. To minimize trauma risk and facilitate secure bonding with the mask portion, the tube was covered with a silicone sheath giving an od of 17.6 mm, apart from its distal or outer end which was accurately pressed into a standard 15 mm connector shape. The maximum od (20 mm) occurs in the plane of the curvature of the tube at the point where it is overlapped by the proximal part of the cuff. Unlike the standard LMA tube, which had to protrude sufficiently from the mouth to be gripped easily and to permit stabilization by bending down over the chin, the rigid metal tube with its gripping handle could be made shorter, terminating close to the mouth. Thus the relative shortness and increased id of the tube allowed passage of an adult sized TT to its correct depth, overcoming the main disadvantage of the standard LMA as an intubating guide.

The stainless steel handle welded to the outer end of the tube proximal to the 15 mm connector facilitated device manipulation and made it possible to perform insertion without placing the fingers in the mouth. The handle was stiff but malleable, permitting some adjustment of the angle it made with the tube.

The distal end of the tube was not cut squarely but had a 30° bevel anteriorly, in order to permit compression of the device at its widest point for patients with reduced inter-dental distance.

EPIGLOTTIC ELEVATING BAR

As both the epiglottis and the bars across the LMA aperture may impede passage of a TT through the LMA,[7] the bars were replaced with a single central bar, or epiglottic elevating bar (EEB), attached only at the upper rim of the mask so that its free end could be swung out by the advancing TT, pushing the epiglottis out of the way as it did so. Critical to performing this function was the level of the EEB tip in the pharynx, as it has to lie deeply enough to engage with the epiglottis but not so deep that it became wedged posterior to the caudal rim of the glottic aperture. In order to arrive at the correct position and size of the EEB, the pharyngeal level of the epiglottis in each of the MRI views was measured. Epiglottic depth was expressed as the distance between the free end of the epiglottis and the dome of the hard palate (PE distance), measured along a line drawn parallel to the first five cervical vertebrae and a line at right angles to this line passing

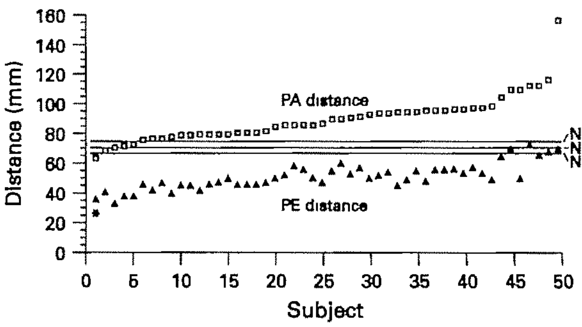

Figure 3 Palato-arytenoid distance (PA) and palato-epiglottic distance (PE) in each of the 50 MRI subjects. The gap between PA and PE represents the size of the glottic aperture in the cephalo-caudal axis. The horizontal lines represent distances of the tip of the epiglottic elevator bar (EEB) from the dome of the hard palate for the three sizes of the ILMA, measured along the same axis. In only one subject (*) was the glottic aperture too high for all three sizes of the LMA.

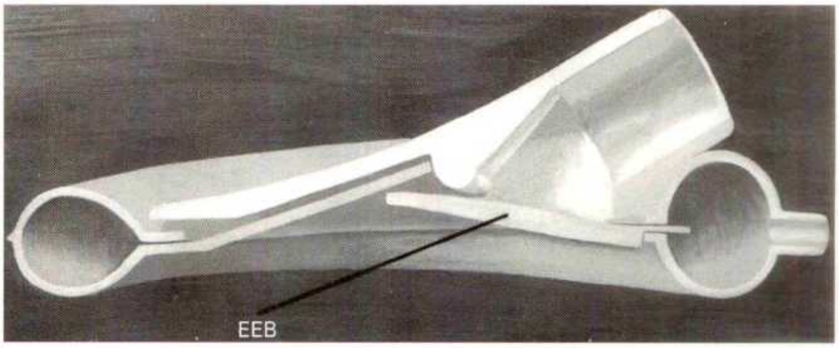

Figure 4 A prototype ILMA sectioned longitudinally in the mid-line to show the arrangement of the guiding ramp. EEB=Epiglottic elevator bar.

tangential to the dome of the hard palate. The distance between the hard palate and the arytenoid cartilages was also measured along the same axis (PA distance) (fig. 2). The length of the glottic aperture was then calculated (PA–PE). The length of EEB which would bring the EEB tip most reliably into a position behind the epiglottis where it could act as an epiglottic lever could then be determined. Keeping the size of the tube constant, three sizes of mask were used, into each of which an EEB was fixed proportional to the size of the mask. The mask sizes corresponded to sizes 3, 4 and 5 of the standard LMA. After tracing the predicted position of each mask size onto tracings of the MRI pictures, a suitable length of EEB was arrived at, such that the EEB tip rested at the approximate mid-point in the bowl of each size of mask. Assuming the airway tube lay in contact with the palatal dome, the relative distances from the tip of the EEB to the highest point or apex of the palatal dome for the three sizes of the ILMA were measured along the same axis as PE distance. These distances were 67, 71 and 75 mm for sizes 3, 4 and 5 ILMA, respectively. A plot of PE and PA measurements in the 50 subjects showed that for all except one subject the position of the EEB tip came to lie within the glottic aperture for at least one of the three sizes of ILMA (fig. 3).

TRACHEAL TUBE GUIDING RAMP

In order to direct the TT anteriorly as it emerged from the mask aperture, the passage immediately behind the EEB was provided with a 20° ramp in its floor (fig. 4). This gave a 47° angle with the plane of the mask cuff. The posterior floor of the ramp was contoured in a "V" instead of a "U" shape in order to centralize tubes passed through it irrespective of diameter; this avoided the problem of TT being deviated to the left or right when they impinged on the EEB.

TRACHEAL TUBE

Direct laryngoscopy requires distortion of the anatomy to obtain a line of sight from the mouth to the vocal cords. The TT has traditionally been shaped to facilitate its placement when the head, neck and anterior pharyngeal structures have been distorted. On encountering the laryngeal inlet, a TT is required to reverse its curvature by approximately 30° from the plane of the inlet to pass into the trachea. In view of this it was clearly undesirable to use a TT the natural curvature of which was in the reverse direction. Moreover, polyvinylchloride (PVC) TT were found to retain the additional curvature imposed on them by the ILMA tube. Bench testing using standard PVC TT showed that PVC significantly retained the curvature imposed by passage through the metal tube and that this effect was retained even when the tubes were warmed to 37 °C (fig. 5). This effect was not seen with silicone tubes. Therefore, it appeared logical to use straight, soft, cuffed silicone TT when intubating through the ILMA device. Accordingly, prototype 8 mm id cuffed silicone TT were prepared (Accusil Inc, IN, USA). These were marked transversely with a depth marker to show the user the point at which the tip of the TT was about to lift away the EEB. In addition, a longitudinal line similar to the black line on an LMA tube was provided to serve as a guide to the

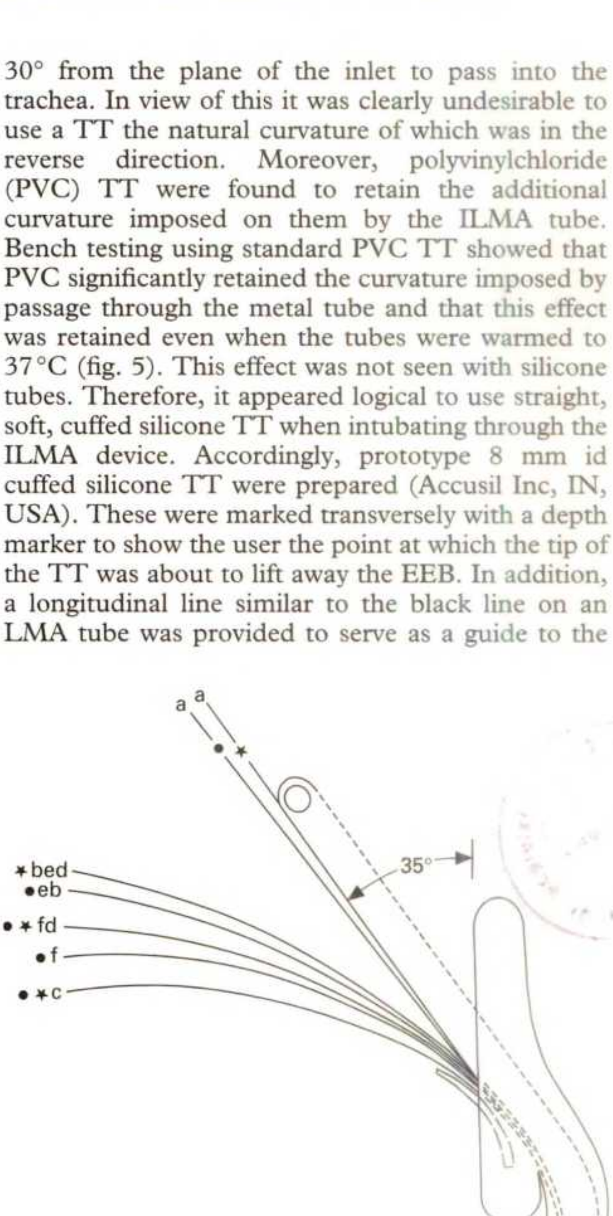

Figure 5 Effect on tracheal tube curvature for different tubes at 25 °C (●) and 37 °C (★) when passed through the ILMA tube: a=straight silicone 8 mm; b=curved Euromedical PVC 8 mm; c=Rusch red rubber 8 mm; d=Portex PVC 8 mm; e=Mallinkrodt PVC 8 mm; and f=Mallinkrodt PVC reinforced 7 mm.

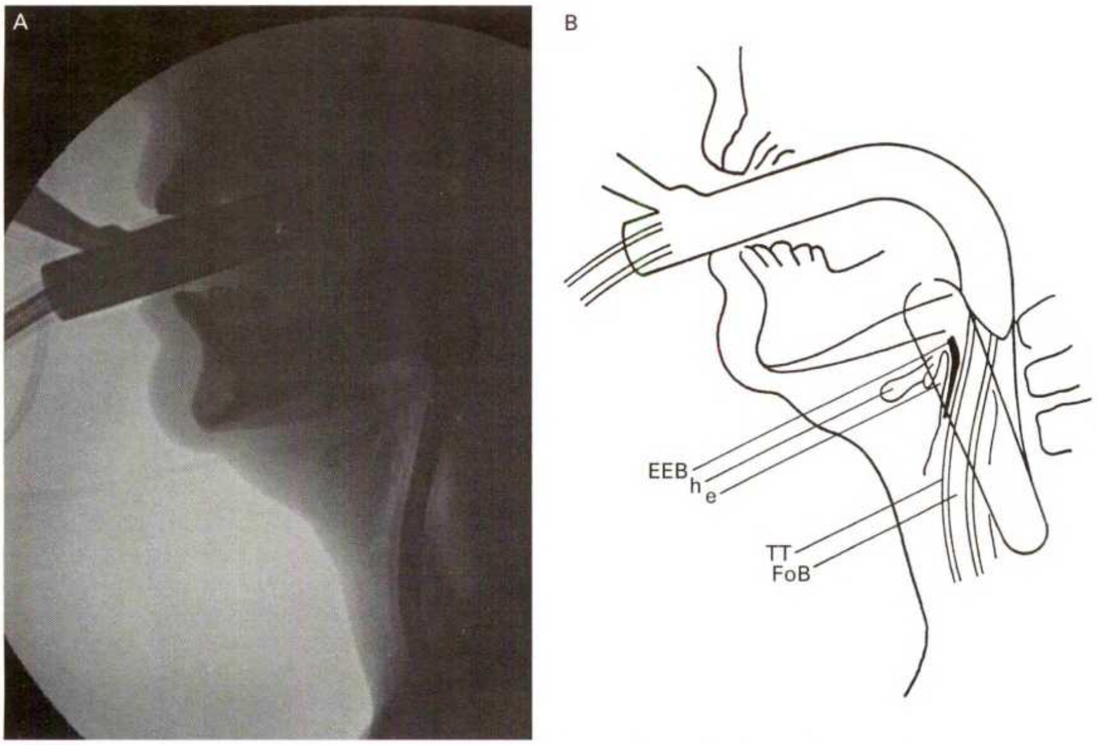

Figure 6 Soft tissue radiograph with explanatory drawing of a patient's trachea intubated through the ILMA. A fibreoptic scope had been passed through the straight silicone tube subsequently. EEB=Epiglottic elevator bar; h=hyoid; e=epiglottis; TT=straight silicone tracheal tube; and FoB=fibreoptic bronchoscope.

orientation of the TT bevel. The pilot balloon and valve were small enough to pass easily through the metal tube of the ILMA, and the TT connector was removable (standard connectors are too large to pass through the ILMA tube) in order that the ILMA could be removed from the patient when intubation has been achieved.

Figure 6 is a soft tissue radiograph with explanatory drawing showing a patient's trachea intubated through the device using a silicone tube, through which a fibrescope has been passed. The EEB can be seen displacing the epiglottis anteriorly.

Discussion

We have described the further development of an ILMA prototype to aid tracheal intubation.

Our initial studies with a modified LMA[6] indicated that with manipulation of the head and neck it was possible to place a TT blindly while maintaining ventilation by connecting the TT to the anaesthesia system. With the further development of the ILMA, several potential advantages compared with conventional laryngoscopy and intubation are apparent. The standard tracheal tube is subject to distortion stresses when in place which, as Lindholm pointed out, are transmitted to the anatomy.[8] This factor combined with the distortion stresses inherent in laryngoscopic manipulation make it unsurprising that the conventional practice of tracheal intubation is associated with significant morbidity.[9] The ILMA design allows a soft, flexible, silicone tube to be directed towards the plane of the glottis without distortion of the anatomy. Further, the ILMA is inserted without manipulation of the head and neck.

Circulatory responses to direct laryngoscopy and tracheal intubation were first described in 1951[10] and since then much work has focused on ways to attenuate these responses. It has been shown that placement of the LMA is associated with a reduced stress response compared with the TT[11 12] and this may be advantageous in those patients likely to be adversely affected, such as those suffering from hypertension or ischaemic heart disease, or both. It is possible that tracheal intubation through the ILMA may be less stimulating than conventional laryngoscopy, but this remains unsubstantiated. Ease of placement without head and neck manipulation and without the need for the rescuer to be positioned behind the head or to insert fingers into the mouth, together with its ability to serve as a sole airway suggest a role in emergency medicine. This role is made more attractive by the possibility of subsequently being able to insert an appropriate sized TT through the device without first having to remove it. Finally, inability to ventilate a patient's lungs during attempts at TT placement remains an unsolved problem in anaesthesia. We believe this ILMA prototype has the potential to help alleviate this problem, not only by permitting continued ventilation during intubation attempts, but because avoidance of the need to obtain a line of sight should in theory eliminate the major cause of such difficulties. Our preliminary clinical experience with this device in 150 patients with routine and abnormal airways is reported subsequently.[13]

Acknowledgement

We thank the Department of Radiology at the Royal Berkshire Hospital for their assistance in making available the MRI and Dr J. Brimacombe for advice.

The intubating laryngeal mask. II: a preliminary clinical report of a new means of intubating the trachea

A. I. J. BRAIN, C. VERGHESE, E. V. ADDY, A. KAPILA AND J. BRIMACOMBE

Summary

We have assessed the efficacy of a new laryngeal mask prototype, the intubating laryngeal mask airway (ILMA), as a ventilatory device and blind intubation guide. The ILMA consists of an anatomically curved, short, wide bore, stainless steel tube sheathed in silicone which is bonded to a laryngeal mask and a guiding handle. It has a single moveable aperture bar, a guiding ramp and can accommodate an 8 mm tracheal tube (TT). After induction of anaesthesia with propofol 2.5 mg kg^{-1} and fentanyl 2.5 μg kg^{-1}, the device was inserted successfully at the first attempt in all 150 (100%) patients and adequate ventilation achieved in all, with minor adjustments required in four patients. Placement did not require movement of the head and neck or insertion of the fingers in the patient's mouth. Blind tracheal intubation using a straight silicone cuffed TT was attempted after administration of atracurium 0.5 mg kg^{-1}. If resistance was felt during intubation, a sequence of adjusting manoeuvres was used based on the depth at which resistance occurred. Tracheal intubation was possible in 149 of 150 (99.3%) patients. In 75 (50%) patients no resistance was encountered and the trachea was intubated at the first attempt, 28 (19%) patients required one adjusting manoeuvre and 46 (31%) patients required 2–4 adjusting manoeuvres before intubation was successful. There were 13 patients with potential or known airway problems. The lungs of all of these patients were ventilated easily and the trachea intubated using the ILMA. In 10 of 13 (77%) of these patients, no resistance was encountered and the trachea was intubated at the first attempt; three of 13 (23%) patients required one adjusting manoeuvre. Tracheal intubation required significantly fewer adjusting manoeuvres in patients with a predicted or known difficult airway ($P<0.05$). We conclude that the ILMA appeared on initial assessment to be an effective ventilatory device and intubation guide for routine and difficult airway patients not at risk of gastric aspiration. (*Br. J. Anaesth.* 1997; **79**: 704–709).

Key words
Equipment, masks anaesthesia. Intubation tracheal. Intubation tracheal, technique.

Tracheal intubation using a laryngoscope involves distortion of the anatomy in order to bring the glottis into the line of sight. Sufficient anatomical distortion is not always easy or possible, leading to intubation difficulties in 1–3%[1] and failure in 0.05–0.2% of cases.[2 3] Failed/difficult tracheal intubation remains an important cause of mortality and morbidity in anaesthesia.[4] The laryngeal mask airway (LMA) has an established role in the management of failed intubation.[5 6] Difficulty in viewing the glottis is generally irrelevant for successful LMA placement, making it a useful substitute airway, and the curved tube guides instruments towards the glottis, making it a useful intubation aid. Reported success rates for blind and fibreoptic-guided passage of a tracheal tube (TT) via the LMA vary between 30–93%[7–9] and 96–100%,[10–12] respectively, depending on technique, experience, number of attempts taken and equipment chosen. However, the standard LMA is not an ideal intubation aid as the airway tube is too narrow to accommodate an adult diameter TT, too long to ensure a normal length TT will reach the trachea and not sufficiently rigid to function as a guide to exact alignment of the mask with the glottis. In addition, the mask aperture bars may obstruct passage of the TT. In an attempt to overcome these limitations, a prototype intubating laryngeal mask airway (ILMA) has been developed. Other design goals were to eliminate the need for head–neck manipulation and insertion of fingers in the mouth during placement.

The following preliminary study assesses the safety and efficacy of the ILMA as a ventilatory device and blind intubation guide in patients with normal and abnormal airways.

Methods

APPARATUS

The prototype ILMA is shown in figure 1. The design features and objectives are given in table 1.

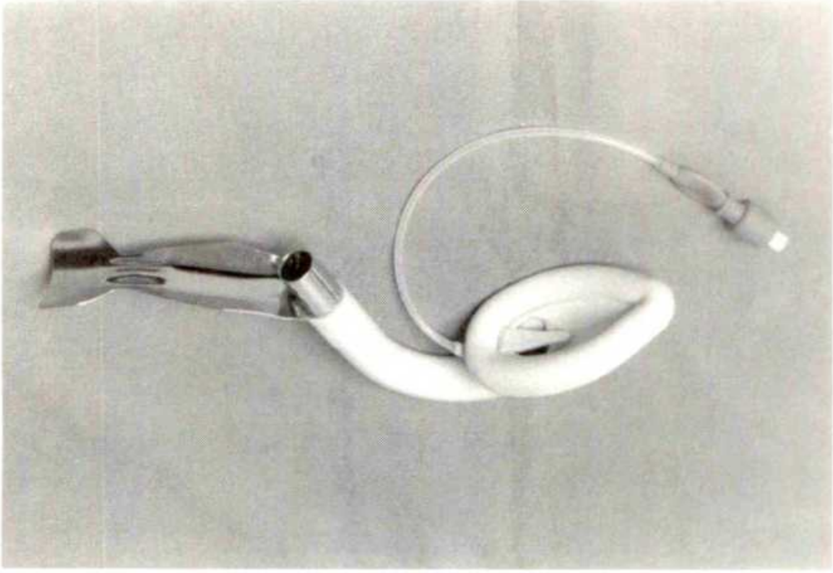

Figure 1 Prototype intubating laryngeal mask.

Table 1 ILMA design features and function

Feature	Function
Rigid stainless steel airway tube	Permits mask to be guided/steadied during intubation Short enough to permit TT to pass to correct depth Good internal: external diameter ratio (13:15 mm) Autoclavable
Integral 15 mm connector	Permits use as standard LMA Avoids danger of accidental disconnection Permits passage of 8.0 mm cuffed TT
Anatomical curve of tube	Permits insertion with mask following same path as with standard insertion technique Avoids need for head and neck manipulation Avoids need to insert finger because pressure against palate can be applied externally Aligns TT to plane of glottic vestibule Permits use of straight TT reducing anterior tracheal wall trauma
Integral tube handle	Allows device manipulation and steadying during intubation–extubation Facilitates device insertion–removal
Bevel on proximal end of stainless steel tube	Permits mask aperture to be compressed to permit passage via narrow inter-dental gap
"V"-shaped TT guiding ramp	Tube centring function Guides tube anteriorly to reduce risk of arytenoid trauma–oesophageal placement
Epiglottic elevating bar (EEB)	Acts as epiglottic ramp during insertion Keeps epiglottis from obstructing airway Protects and elevates epiglottis during tube passage

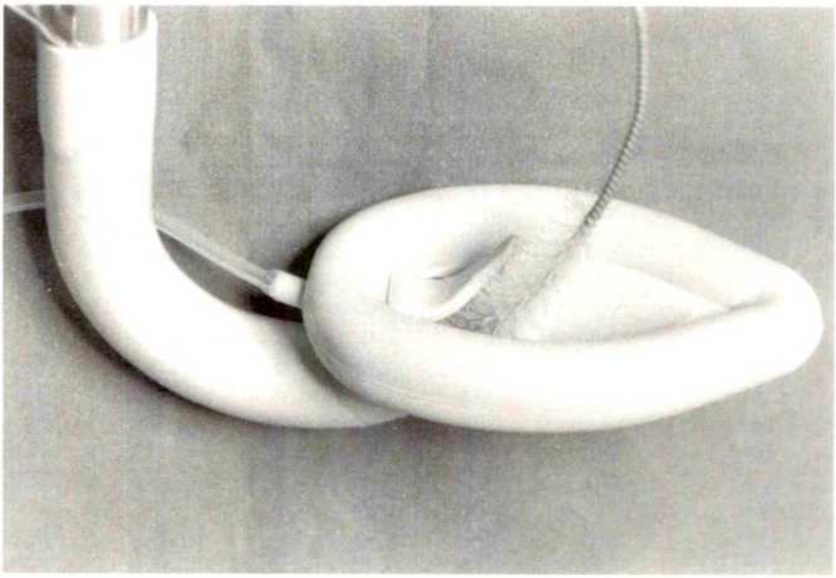

Figure 2 Epiglottic elevator lifted forward by cleaning brush.

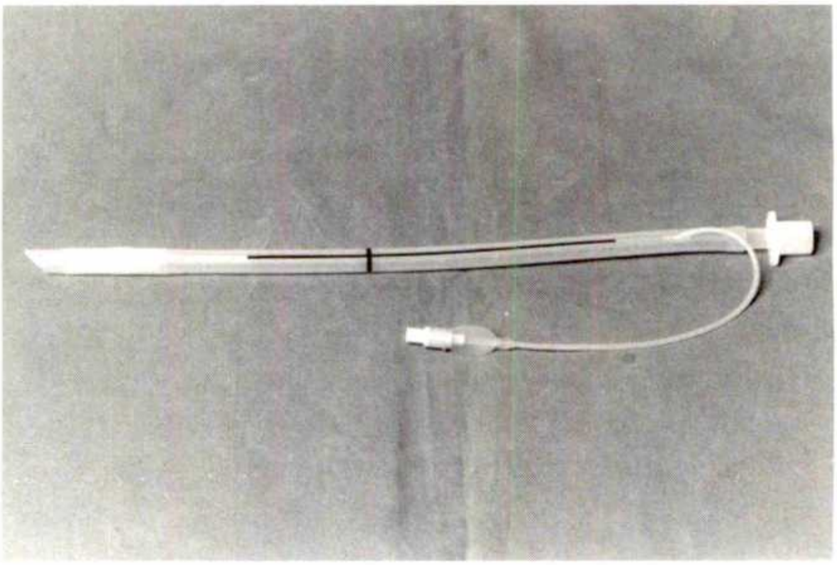

Figure 3 Prototype cuffed silicone tube used in the study.

The form of the tube was derived from MRI studies of 50 normal subjects and differs from that described in an earlier study.[13] Details on design and development of the ILMA and TT are presented in an accompanying article.[14] In brief, the new prototype device consists of an anatomically curved, short, wide bore, stainless steel tube sheathed in silicone which is bonded to a laryngeal mask and a guiding handle (fig. 1). It has a single moveable epiglottic elevator bar (EEB) (fig. 2), a guiding "V"-shaped ramp and can accommodate an 8 mm TT. The TT selected was a prototype straight cuffed silicone tube (Accusil Inc, IN, USA) which was marked transversely to show the user the point at which the tip was about to lift away the EEB (fig. 3). This marker was used as a reference point when measuring the depth at which resistance was felt during insertion. In addition, a longitudinal line similar to the black line on an LMA tube was provided to serve as a guide to the orientation of the TT bevel. With this line facing cephalad, the tube bevel faced to the left.

CLINICAL STUDY

This multicentre study received Ethics Committee approval and informed consent was obtained from all patients. We studied 150 patients undergoing general, orthopaedic or peripheral plastic surgery who required tracheal intubation. Patients were excluded if they were less than 18 or more than 90 yr of age, ASA IV–V, had respiratory tract pathology or were at risk of regurgitation–aspiration (previous upper gastrointestinal tract surgery, known or symptomatic hiatus hernia, oesophageal reflux, peptic ulceration or not fasted). Patients with potential or known airway problems with an inter-dental gap of >2.5 cm were recruited for the study where possible.

Standard monitoring was applied before induction and included ECG, pulse oximeter, capnography and non-invasive arterial pressure monitor. The lungs of all patients were preoxygenated for 3 min and fentanyl 2.5 μg kg^{-1} given i.v. followed 1 min later by propofol 2.5 mg kg^{-1} over 30 s. Patients' lungs were ventilated by face mask for 30 s with 100% oxygen and the ILMA inserted when the eyelash reflex was lost and the jaw relaxed. Additional boluses of propofol 0.5 mg kg^{-1} were given as required until an adequate level of anaesthesia was achieved for placement of the ILMA. Anaesthesia was maintained with isoflurane and nitrous oxide in oxygen. A size 4 and size 5 ILMA were available for the study. Size selection was at the discretion of the anaesthetist, but the size 4 was used for normal adults (30–70 kg) and the size 5 for large adults (>70 kg). All ILMA were inserted by experienced LMA users who had placed the ILMA on more than 10 occasions before the study.

The insertion technique consisted of a one-handed rotational movement in the sagittal plane with the head supported by a pillow to achieve a neutral position. Specifically, the mask was fully deflated with the rim facing posteriorly, a bolus of a water soluble lubricant applied posteriorly to the distal saucer-shaped tip, which was then flattened against the palate with no attempt made to push the device inwards until the saucer-shaped depression had been seen to be inverted against the palatal surface, drawing back slightly to ensure complete flattening of the rim into the dome of the palate. The ILMA was then rotated inwards, following the arc of the palate and posterior pharyngeal wall so that the curved tube remained closely applied to the inner aspect of the upper incisors throughout the insertion manoeuvre. After insertion, using a hand-held cuff inflator–manometer, the device was inflated to an intracuff pressure of 60 cm H_2O without holding it in place and ventilation was attempted by squeezing the reservoir bag. Successful placement–ventilatory ability was judged by chest wall movement and capnography (maintain PE'_{CO_2} within normal range) during manually assisted ventilation. If adequate ventilation was not possible the ILMA was manipulated *in situ* before removal and reinsertion.

When an adequate airway was established, patients were given atracurium 0.5 mg kg^{-1} and after

Table 2 Probable cause of resistance and appropriate management strategy at a variety of depths measured from the transverse marker on the tracheal tube (reflects distance of tracheal tube tip from bowl). EEB=epiglottic elevating bar, TT=tracheal tube, ILM=intubating laryngeal mask

Depth of resistance	Probable cause	Management
0–1.5 cm	EEB trapped behind cricoid cartilage	Use smaller ILMA
1.5–2 cm	Epiglottis down folded	TT removed. ILMA swung back outwards no more than 6 cm without deflating the cuff, then repositioned (up–down manoeuvre)
2–4 cm	EEB lying too high and unable to engage with the cephalad tip of the epiglottis	Use larger ILMA
4–6 cm	TT tip was wedged between the inflated mask tip and the cricoid cartilage	Use smaller ILMA

3 min the lubricated silicone TT was inserted into the metal tube of the ILMA, moving it up and down to distribute the lubricant until it was sliding freely, but without allowing the transverse line on the TT to pass within the metal tube. The TT was then connected to the anaesthesia breathing system to permit ventilation during and between intubation attempts. Tracheal intubation was attempted using a standardized design. The design was based on MRI data which suggested that different malpositions might be detected by noting the depth in relation to the transverse marker at which passage of the TT became blocked. An appropriate adjusting manoeuvre could then be attempted. After ensuring the longitudinal line on the TT was facing cephalad and grasping the handle of the ILMA to maintain it in the optimum ventilating position, the TT was passed carefully approximately 1.5 cm beyond the transverse marker. If no resistance was felt the downward movement of the TT was continued while observing signs of tracheal placement (end-tidal carbon dioxide trace and chest wall movement during ventilation). After inflating the TT cuff, manual ventilation was commenced gently and capnographic confirmation of TT placement was sought. In the absence of expired carbon dioxide, oesophageal placement was diagnosed and the tube removed immediately to re-establish ventilation through the ILMA. If resistance was felt the depth was noted and a variety of strategies were instituted based on probable cause (table 2). If the attempt failed, other manoeuvres were used including: optimizing the airway (steering the mask with the handle while squeezing the reservoir bag with the Heidebrink valve closed, until an optimal airway was obtained), raising the mask upwards, partial withdrawal, rotating the TT bevel, adjusting head–neck position or adding air to the cuff. When tracheal intubation was successful, the ILMA was removed using a 25 cm length tube, cut from an 8 mm silicone TT as a "pusher" to prevent accidental extubation while the device was being withdrawn.

The following data were recorded: age, weight, height, sex, potential or known airway difficulty, ILMA size used, number of attempts at ILMA insertion, airway complications during placement, ventilatory capability, number of adjusting manoeuvres (a maximum of four was considered an acceptable number in view of the potential of the device to permit continuous ventilation whether or not intubation succeeded), problems encountered and successful solutions during intubation, and problems with device removal. Finally, any episodes of oxygen saturation <95% were noted up to the point where the ILMA was removed and the TT secured.

Statistical analysis was with the Student's *t* test and chi-square test. Significance was taken as $P<0.05$.

Results

Mean age, height and weight were 56 (range 19–85) yr, 169 (153–188) cm and 73 (40–183) kg, respectively. The male:female ratio was 78:72. Placement of the ILMA was successful at the first attempt in all patients, but four (2.7%) required device repositioning to achieve adequate ventilation. There were no adverse airway events during placement. Tracheal intubation was successful in 149 of 150 (99.3%) patients: 75 (50%) at the first attempt, 28 (19%) required one adjusting manoeuvre, 21 (14%) required two, 18 (12%) required three and seven (5%) required four. Sizes 4 and 5 were used initially in 113 (75%) and 37 (25%) patients, respectively. On 10 (7%) occasions the size 4 was exchanged for a size 5 and on one (1%) occasion the size 5 exchanged for the size 4. Mean weight and height for the size 4 were 69 (range 40–183) kg and 164 (155–180) cm, respectively, and for the size 5, 85 (68–130) kg and 176 (158–188) cm, respectively.

Manoeuvres used to achieve successful intubation included: the up–down manoeuvre (61%), optimizing the airway (22%), change of size (7%), raising the mask upwards (4%), partial withdrawal (2%), rotating the bevel (2%), adjusting head–neck position (1%) and adding air to the cuff (1%). Oxygen saturation decreased to less than 95% after ILMA insertion on only two occasions. In one patient, a muscular man of 105 kg and height 153 cm, intubation attempts resulted in a decrease in saturation to 85% and further attempts were abandoned. The 25 min case was concluded using the ILMA as the sole airway. Oxygen saturation was maintained at 90%, but increased to normal levels during recovery, with no adverse sequelae. The second patient, a heavy smoking 146-cm, 76-kg female, developed bronchospasm during intubation attempts. Oxygen saturation decreased to 87% and resolved rapidly after deepening of anaesthesia. Intubation through the ILMA was accomplished easily and there were no further problems. No

problems were encountered in removing the ILMA over the tube when tracheal intubation had been accomplished. No cases of major soft tissue damage or dental trauma occurred as determined by a lack of blood on removal of the device and routine postoperative questioning. The incidence of sore throat was not assessed formally.

There were 12 patients recruited with potential or known airway problems and one airway problem was encountered during the study (table 3). The lungs of all of these patients were ventilated easily using the ILMA and the trachea intubated subsequently through the ILMA without loss of airway control. In 10 of 13 (77%) patients, the trachea was intubated at the first attempt and in three of 13 (23%) patients one adjusting manoeuvre was required. The success rate of patients without a potential or known difficult airway was 65 of 137 (47%) at the first attempt. Tracheal intubation required significantly fewer adjusting manoeuvres in patients with a potential or known difficult airway (10 of 13 *vs* 65 of 137; chi-square=4.13, $P<0.05$).

Discussion

This preliminary unblinded study has shown that the ILMA is an effective ventilatory device and blind intubation guide for normal sized TT in anaesthetized patients with routine and difficult airways. The success rate as a ventilatory device (100%) was comparable with the standard LMA (>98%).[15–17] The success rate as a blind intubation guide (99%) was higher than the standard LMA (19–93%)[7–9 12] and an earlier prototype ILMA (93%),[13] and similar to fibreoptic-guided intubation via the standard LMA (97–100%).[10–12] Studies are currently underway to determine the success rate of the ILMA as an aid to fibreoptic-guided intubation.

It is likely that the procedure to determine the appropriate adjusting manoeuvres will be refined as experience increases. The tactic of optimizing the airway (first suggested by C. V.) was highly effective and may be a more logical approach than allowing the device to self-locate or changing size. It is possible that the "up–down" manoeuvre was beneficial not because the epiglottis was down folded, but because the larynx might have been initially displaced downwards. It is also possible that the TT bevel was catching on the lateral vestibular wall in some cases where epiglottic down folding was thought to be the cause of the problem. This does not appear to have occurred in earlier LMA studies[8 9] and may be because of the smaller diameter of tubes used with the standard device (sizes 3 and 4), as they are less likely to become caught against the glottic anatomy. A logical design modification would be to arrange for the bevelled tip of the TT to point in the mid-line or make the tip curved like a Tuohy needle and this has now been done. Another possible unrecognized cause of failure was the presence of a narrow epiglottis which might slip to one or other side of the EEB. This was observed fibreoptically by another investigator using an identical ILMA (D. Ferson, personal communication, MD Anderson Center, Houston, TX, USA).

The ILMA offers several advantages and disadvantages over the standard LMA. The ILMA overcomes the diameter–length limitations for TT imposed by the standard LMA and facilitates guidance of the TT towards the glottis. The ILMA does not require head–neck manipulation (use in cervical spine pathology) or insertion of the fingers in the patient's mouth (less risk for damaging the practitioners fingers–infection transmission) for successful placement. The insertion technique is conceptually simpler and may be achieved using the same rotational manoeuvre from any position (useful when access is limited). The wide, short tube should offer less work of breathing and allow passage of larger instruments into the respiratory tract. Although the fixed length and rigid tube means that the tip may not necessarily sit in the correct position, the guiding handle allows an optimal airway to be sought out and additional force applied to the periglottic tissues if a higher pressure seal is transiently needed. Other disadvantages are that the ILMA is unsuitable used alone for most head, neck, ENT and dental surgery (the handle sticks out and the wide rigid tube occupies the mouth), the seal may change if the head–neck is moved and it cannot be inserted if the inter-dental distance is less that 20 mm (maximal od of ILMA). In theory, the rigid tube might be more traumatic to teeth and a higher incidence–different type of sore throat. Trauma of teeth caused by biting may be prevented by use of a thick roll of gauze swabs. This also facilitates stabilization of the ILMA in the mouth.

The ILMA offers several advantages for difficult airway management. First, the difficulty in viewing the larynx which often underlies failed laryngoscopic intubation is probably irrelevant to ILMA placement and subsequent intubation. Placement of the standard LMA is probably independent of factors used to predict[18 19] or score[20] difficult intubation and the success rate of LMA placement in the abnormal airway has been reported at 97–100%.[10–12] Our data suggest that ILMA placement is similarly easy, although numbers are limited. The finding that tracheal intubation was easier in the abnormal airway requires further assessment, but it is possible that the high anterior larynx associated with Cormack and Lehane III and IV[21] may facilitate better alignment of the ILMA tube and glottic aperture. Second, the ILMA allows ventilation to be continued during intubation attempts, minimizing the risk of hypoxaemia and allowing an unhurried approach to securing the airway. Third, no movement of the cervical spine is required with the ILMA and this may be important for patients with cervical spine pathologies as placement can be accomplished in the neutral position. Fourth, placement of the ILMA and subsequent intubation are blind techniques (although a fibreoptic scope can be used to place the TT) thus accessory equipment is not required and placement unaffected by heavy secretions or blood which might impair fibreoptic techniques. Finally, placement does not require the practitioner to be above the patient's head.

The intubating laryngeal mask airway: an initial assessment of performance†

A. KAPILA, E. V. ADDY, C. VERGHESE AND A. I. J. BRAIN

Summary

A new prototype of the laryngeal mask airway (LMA), the intubating laryngeal mask airway (ILMA), was used to facilitate tracheal intubation in 100 fasted patients presenting for elective surgery. Alignment of the ILMA with the larynx was assessed fibreoptically before intubation without the investigator performing the intubation being aware of the view score. Ease of intubation correlated with the view obtained and with the degree of manipulation of the ILMA needed to achieve tracheal intubation. Intubation was successful in 93 patients. Of the seven intubation failures, five occurred in the first 20 patients. Conventional connection to the breathing system and ventilation of the lungs of the patients were possible throughout the intubation procedure. (*Br. J. Anaesth.* 1997; **79**: 710–713).

Key words

Equipment, masks anaesthesia. Intubation tracheal. Intubation tracheal, technique.

The laryngeal mask airway (LMA) represents a major advancement in airway management.[1] In addition, it has been used to facilitate tracheal intubation by a variety of methods.[2-9] An early prototype of the laryngeal mask airway was used for intubation in a patient known to present with a difficult tracheal intubation.[10] We describe a new prototype, the intubating laryngeal mask airway (ILMA),[11] and a preliminary assessment of its performance in aiding tracheal intubation in fasted surgical patients.

Patients and methods

The ILMA (fig. 1) incorporates a standard LMA cuff in sizes 3, 4 or 5 and a metal airway tube and handle. The latter allows manipulation of the device within the patient's airway. The airway tube has a wider internal diameter (1.3 *vs* 0.9 cm) and is shorter 14.5 *vs* 20 cm) than the standard LMA tube (size 3 or 4). In addition, there is a silicon rubber bite block surrounding the upper part of the stem. The ILMA admits up to a 9.0 mm cuffed tracheal tube.

After obtaining Ethics Committee approval, informed consent was obtained from ASA I and II adult patients presenting on elective surgical lists. Patients were excluded if they had a history of active gastro-oesophageal reflux, severe respiratory disease or inadequate fasting. After i.v. induction of anaesthesia with fentanyl 1 μg kg^{-1} and a sleep dose of propofol, neuromuscular block was produced with atracurium 0.6 mg kg^{-1}. The lungs were pre-oxygenated and patients were monitored with ECG, capnography, pulse oximetry and a peripheral nerve stimulator. Patients' lungs were gently ventilated manually by face mask and after ablation of the train-of-four response to peripheral nerve stimulation an ILMA of appropriate size to patient weight was introduced (usually a size 4 for females and size 4 or 5 for males). The ILMA was preloaded with a 7 or 8 mm cuffed tracheal tube (TT) (Portex Ltd, Hythe, Kent, UK) with the cuff of the TT tube inflated within the stem of the ILMA to ensure an airtight seal. Before insertion, the cuff of the ILMA was deflated using a cuff deflating device (Intavent Orthofix Ltd, Maidenhead, Berks, UK) to ensure maximal extraction of air yet retaining a smooth cuff profile; the dorsal surface was lubricated with KY jelly (Johnson and Johnson Ltd, Maidenhead, UK). When the ILMA had been inserted by passing the device along the posterior pharyngeal wall, conventional connection of the TT tube to an anaesthetic breathing system and ventilation of the patients' lungs was attempted (fig. 1). Successful placement/ventilatory ability was judged by chest wall movement and capnography (maintain $P\text{E}'_{\text{CO}_2}$ within normal range) during gentle manually assisted ventilation. Inhalation anaesthesia with nitrous oxide and enflurane in oxygen was introduced at this stage.

Alignment of the ILMA with the larynx was assessed by an independent observer using a fibreoptic intubating laryngoscope, (Olympus LF-2, Keymed Ltd, Keymed House, Southend-on-Sea, UK) which was passed through the diaphragm of the tracheal tube connector (Intersurgical, Wokingham, UK) until the tip was lying just inside the ILMA

grill. The view obtained was then graded according to a scoring system (table 1).

Without movement of the patient's head and neck from the "sniffing position", obtained with one pillow, TT tube advancement (by either A. K. or E. V. A.) was attempted using one or more of the following methods: (a) without movement of the ILMA (neutral), (b) pulling back of the metal handle of the ILMA towards the intubator (extension) or (c) pushing the metal handle of the ILMA away from the intubator (flexion). Manoeuvres (b) and (c) achieve a rotatory movement of the ILMA in the sagittal axis within the patient's airway and affect alignment of the mask with the larynx. Ease of intubation was assessed by recording the number of attempts required to intubate the patient's trachea and the final position of the ILMA at the time of TT intubation was noted. Successful intubation was confirmed by capnography during manually assisted ventilation. Failure to intubate was defined as inability to place the TT tube successfully after all three manoeuvres had been attempted. The ILMA was left *in situ* for the duration of the case with the cuff deflated.

Results

We have used the ILMA in 100 patients (30 male). Mean age was 50.1 (range 22–87) yr and mean weight 68.7 (range 40–107) yr. Anaesthesia was uneventful in all patients. Placement of the ILMA and adequate ventilation were achieved at the first attempt in all patients. The trachea was intubated successfully in 93 patients, 72 at the first attempt. Of the 28 patients requiring more than one attempt at TT intubation, difficulties with tube advancement resulted from two causes: either TT tube passage was obstructed (this occurred in 25 patients of which 21 patients were intubated successfully after manipulation (table 2)), or the tube passed into the oesophagus (this occurred in three cases and was recognized by the absence of chest wall movement and the use of capnography). Of the seven failed intubations, five occurred in the first 20 patients. Of the 93 patients with a view score of 1 or 2, there was a 95% success rate at tracheal intubation. Of the five patients with a view score of 3, there were four successful intubations and one failure. Of the two patients with a view score of 4, there was one successful and one failed intubation (table 3). The first was caused by the ILMA being inserted too far, resulting in oesophageal intubation (with only the oesophagus being visible on fibreoptic examination); tracheal intubation was achieved when the ILMA was withdrawn slightly. In the second, the ILMA tip had folded forwards, obstructing tracheal tube advancement and was an intubation failure. This patient was one of the failures occurring after the first 20 patients (late failure). The other late failure was a patient who had a view score of 2 after ILMA insertion, but attempts with all three manipulations of the ILMA still resulted in oesophageal intubation. Removal of one pillow and a less exaggerated "sniffing position" enabled easy intubation subsequently; however, this patient was classified as an intubation failure as the fibreoptic view score was known to the intubator.

Table 2 Attempts at tracheal intubation

Attempts at intubation	No.of patients
1 (no manipulation)	72 (72%)
2 or more (manipulation)	21 (21%)
Failed	7 (7%)

Table 3 Attempts at intubation, classified by fibreoptic view score

	View score			
Attempts at intubation	1	2	3	4
1	47 (85%)	23 (60%)	2 (40%)	0 (0%)
2 or more	6 (11%)	12 (32%)	2 (40%)	1 (50%)
Failed	2 (4%)	3 (8%)	1 (20%)	1 (50%)
	55	38	5	2

As the fibreoptic view score deteriorated, more attempts were required to achieve intubation. When success was achieved in patients with a view score of 1, 2, 3 or 4, six of 53 (12%), 12 of 35 (34%), two of four (50%) and one of one (100%) patients, respectively, required two or more attempts at intubation.

In achieving tracheal intubation in those patients with a view score of 1, the ILMA was manipulated

Table 4 Manipulation of the ILMA in successful intubations according to view score

	View score			
Manipulation	1	2	3	4
Neutral (a)	16	7	0	0
Extension (b)	18	5	2	0
Flexion (c)	19	23	2	1

in approximately equal degree between the manoeuvres (a)–(c) (intubation was successful in 16 patients in the neutral position, in 18 patients after extension and in 19 patients after flexion manoeuvres of the ILMA). As the alignment of the larynx with the ILMA deteriorated (i.e. view scores 2–4), the final position of the ILMA was predominantly flexion (26 patients), rather than neutral (seven patients) or extension (seven patients) (table 4).

Discussion

We have made a preliminary assessment of the performance of a new prototype of the laryngeal mask airway, the ILMA. After insertion of the ILMA in anaesthetized patients, alignment of the ILMA with the larynx was assessed fibrescopically by an independent observer before the attempted passage of a TT tube. A scoring system for the fibreoptic view obtained was based on the direct laryngoscopy grading of Cormack and Lehane[12] and differs from that described by Brimacombe and Berry.[13] It separates view of the larynx from function of the laryngeal mask and is familiar to anaesthetists. Tracheal intubation in 93 of 100 patients was successful. The majority of patients (93) had a view score of 1 or 2 and the trachea was intubated with a success rate of 95%. Of the seven failed intubations, five occurred in the first 20 patients (four with a view score of 1 or 2), demonstrating the presence of a learning curve in acquiring expertise in the use of this prototype of the ILMA. In the five patients with a view score of 3 (only epiglottis visible), four successfully underwent intubation. The degree of device manipulation required to achieve tracheal intubation was related inversely to the view score or alignment with the larynx.

The laryngeal mask airway has been used to facilitate tracheal intubation by a variety of methods.[2–8] It has been recommended as a conduit for fibreoptic intubation for training purposes[14] and for the management of some patients with difficult airways.[15] The salient feature is the possibility of maintaining an airway and oxygenation of the patient throughout the intubation procedure. However, the standard LMA only admits up to a 6.0 mm cuffed tracheal tube. In addition, the cuff of such a tube will not reliably come to lie in the trachea below the vocal cords[16] because of the length of the stem of the LMA. Attempts to overcome these problems have involved cutting and altering the standard laryngeal mask airway.[14 17] The design of the ILMA with its shorter and wider airway tube attempts to overcome these problems and admit up to a 9.0 mm cuffed TT tube.

In this study patients were paralysed (only after it was confirmed that manual ventilation using a face mask was possible), however if neuromuscular blocking agents were not used it may be that in those patients requiring more than one attempt at TT intubation this degree of airway manipulation could provoke laryngeal spasm. In a case of difficult intubation where neuromuscular blocking agents are usually avoided there are two options with this device. First, the ILMA may be inserted and intubation achieved with the patient awake using topical anaesthesia (personal communication L. Loh, Oxford and D. R. Uncles, Worthing). Second, the ILMA may be inserted after induction of anaesthesia and adequate ventilation of the patient's lungs confirmed before administration of a neuromuscular blocker.

The ILMA as an intubating aid may be criticized for being a "blind-on-blind" technique (i.e. both the ILMA and TT tube are inserted without direct sight of the larynx). However, other blind techniques for intubation have been described[18 19] and blind intubation through the standard LMA has been demonstrated successfully.[3] Moreover, fibrescopy may be performed either before or during the intubation attempt if the equipment is available. With the ILMA, manipulation of the rigid tube and handle is transmitted directly to the inflatable cuff, altering its position within the patient's airway, unlike the standard LMA or more particularly the reinforced LMA. We believe that this manipulation enabling alignment of the ILMA with the laryngeal inlet to facilitate tracheal intubation while being able to ventilate the patient's lungs throughout the procedure may represent a valuable advance over current intubation aids.

Skin vasomotor reflex induced by laryngoscopy: comparison of the McCoy and Macintosh blades

O. SHIMODA, Y. IKUTA, S. ISAYAMA, M. SAKAMOTO AND H. TERASAKI

Summary

We studied 22 female patients (ASA I or II) to investigate if laryngoscopy and intubation induced the skin vasomotor reflex (SVmR), and to compare the effects of the McCoy and Macintosh blades on the SVmR. Anaesthesia was induced with fentanyl, midazolam, vecuronium and nitrous oxide. In 11 patients, the vocal cords were seen for 3 s with the McCoy blade. Two minutes later, laryngoscopy was performed with the Macintosh blade and the trachea was intubated. In the other 11 patients, the first and second laryngoscopies, respectively, were performed with the Macintosh and McCoy blades. Laryngoscopy alone and intubation with laryngoscopy significantly reduced skin blood flow in the ring finger of all patients ($P<0.01$), indicating that both procedures provoked the SVmR. The magnitude of the SVmR and haemodynamic changes did not differ significantly between the two groups. (*Br. J. Anaesth.* 1997; **79**: 714–718).

Key words
Anaesthetic technique, laryngoscopy. Larynx, laryngoscopy. Measurement techniques, flowmetry. Skin, blood flow.

Although many investigators have documented a relationship between detrimental circulatory responses and intubation with direct laryngoscopy,[1–7] there have been few reports of changes in skin blood flow during these procedures. The recent development of the laser Doppler (LD) flowmeter provides a useful tool for observation of skin vasomotion. LD skin blood flow (LD-SBF) is composed of three components: cardiac, basic and reflex waves.[8] The reflex wave that follows an inspiratory gasp or various other somatosensory stimuli manifests as a transient marked reduction in LD-SBF,[8–10] and this has been termed the skin vasomotor reflex (SVmR).[9] We found recently that various surgical stimuli provoked the SVmR, even under general anaesthesia. As the SVmR is transferred to skin vessels via sympathetic nerves,[11–13] it would represent the magnitude of the stress response as a somato-sympathetic reflex when the SVmR is induced by somatosensory stimulation. The main purpose of this study was to investigate if laryngoscopy and intubation induce the SVmR as a stress response.

McCoy, Mirakhur and McCloskey reported that circulatory responses to laryngoscopy were less marked with the use of the McCoy blade compared with the Macintosh blade,[14] suggesting that a decreased stress response results from less force being necessary with the McCoy blade during laryngoscopy.[15] The second purpose of the study was to compare the McCoy and Macintosh blades regarding the magnitude of the SVmR and the circulatory responses during laryngoscopy and intubation.

Patients and methods

The study was approved by the Institutional Review Board of our hospital, and written informed consent was obtained from all patients. We studied 22 patients undergoing elective gynaecological surgery under general anaesthesia with tracheal intubation. All patients were ASA I or II. Patients were allocated randomly to a McCoy–Macintosh (McC–Mac) ($n=11$) or Macintosh–McCoy (Mac–McC) ($n=11$) group. Patients with signs of autonomic dysfunction or cardiovascular disease detected by routine clinical laboratory tests and preanaesthetic interview were excluded because the SVmR is suppressed significantly in patients with autonomic neuropathy.[9 10 16] No patient was receiving chronic medication, was obese (body mass index more than 26 kg m^{-2}) or had an anticipatory difficult airway.

Atropine 0.5 mg i.m. and either hydroxyzine 1 mg kg^{-1} or midazolam 0.08 mg kg^{-1} were administered to patients 30 min before they entered the operating room. In the operating room, the lead CM5 electrocardiogram (ECG) and pulse oximeter were monitored using a Datex AS/3 anaesthesia monitor (Helsinki, Finland). Heart rate (HR) was measured by the moving average method, which used 4 beats if HR was less than 99 beat min^{-1} and 8 beats if HR was equal to or more than 100 beat min^{-1}. Tonometric arterial pressure (TAP), which has been reported to have an excellent correlation with invasive arterial pressure,[17] was measured by the

Nippon Colin BP-508-type S tonometer (Komaki, Japan). The tonometer sensor was attached to the left wrist over the radial artery and calibrated at intervals of 2.5 min by an oscillometric cuff attached to the right upper arm. Arterial pressure was monitored continuously and recorded by a heat pen recorder. Ambient temperature was maintained at 25–26 °C.

An i.v. cannula was inserted into the median antecubital vein of the right arm for infusion of Ringer's lactate solution and drug administration. General anaesthesia was induced with fentanyl 3 μg kg^{-1} i.v. and midazolam 0.1 mg kg^{-1} i.v. After loss of consciousness, vecuronium 0.1 mg kg^{-1} was administered. Subsequently the patient's lungs were ventilated via a face mask with 50% nitrous oxide in oxygen through a semi-closed anaesthesia system. End-tidal concentrations of carbon dioxide and nitrous oxide, obtained from the Y-piece of the anaesthesia system, were monitored by the AS/3 system. Neuromuscular block was monitored by transcutaneous electrical stimulation of the right ulnar nerve (Innervator, Fisher and Paykel, Auckland, New Zealand).

In the McC–Mac group, laryngoscopy was performed with the McCoy blade (size 3) after complete neuromuscular block was achieved (laryngoscopy-1). The standard manner, including "levering"[18] of the McCoy blade, was used. After a clear view of the vocal cords was obtained (grade I view defined by Cormack and Lehane) for 3 s, laryngoscopy was discontinued. The patient's lungs were ventilated again via the face mask with 50% nitrous oxide in oxygen for 2 min. Laryngoscopy was then performed with the Macintosh blade (size 3) and the trachea was intubated immediately (intubation with laryngoscopy-2). In the Mac–McC group, the same procedures were performed but the laryngoscopies were performed with the Macintosh and McCoy blades, respectively. We changed the blade with each laryngoscopy to reduce the bias of the anaesthetist concerning the blades. One of two trained anaesthetists who were familiar with each blade was allocated randomly to the groups. They were blinded to the results of skin blood flow (described later) and changes in arterial pressure and heart rate.

MONITORING LASER DOPPLER SKIN BLOOD FLOW (LD-SBF)

For monitoring LD-SBF we used an LD flowmeter (ALF 2100, Advance, Tokyo). A plate-type probe was attached to the palmar side of the left ring fingertip by double-sided adhesive disk. Details of the LD flowmeter have been described previously.[8–10] The fingertip has rich arteriovenous anastomoses innervated with sympathetic fibres.[10 19] We selected the ring finger to reduce artefacts of the tonometer sensor on the LD-SBF wave because blood flow to the ring finger is supplied predominantly by the ulnar artery. The output signal of the LD flowmeter was recorded on a heat pen recorder at a time constant of 1.0 s.

Ambient temperature, finger temperature, mental strain and the condition of the skin contacting the probe can influence vasomotion.[10 19] Therefore, before induction of anaesthesia, the SVmR was tested by an inspiratory gasp to detect any subclinical vasomotor disorder or probe factor.[8–10] Patients lacking the SVmR were excluded from further study. After induction of anaesthesia, a marked reduction in the LD-SBF following each procedure was recognized as the SVmR (fig. 1).[8–10]

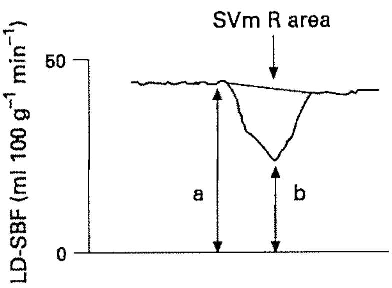

Figure 1 Measurement of the skin vasomotor reflex (SVmR). a=Laser-Doppler skin blood flow (LD-SBF) immediately before laryngoscopy; b=minimal LD-SBF during laryngoscopy or tracheal intubation. The reduction ratio of SVmR (SVmR-RR) was calculated by the equation described in the text The area over the LD-SBF wave and under the tangent line drawn between the drop point and recovery point was measured as SVmR area.

The LD-SBF wave recorded on a heat pen recorder was scanned by a ScanJet IIc with DeskScan II software (Hewlett Packard, Palo Alto, CA, USA) and saved in the TIFF format. Analysis of the magnitude of the SVmR was performed on a Power Macintosh 8500/120 computer (Apple, Cupertino, CA, USA) using the public domain NIH image program (developed at the US National Institutes of Health and available from the Internet by anonymous FTP from zippy.nimh.nih.gov or on floppy disk from the National Technical Information Service, Springfield, VA, part number PB95-500195GEI). We used two indices to quantitatively evaluate the magnitude of the SVmR. The reduction ratio in the SVmR (SVmR-RR) was calculated using the following equation (fig. 1)[9 10 16]:

$$\text{SVmR-RR} = 1 - b / a$$

where a=LD-SBF immediately before laryngoscopy and b=minimal LD-SBF during laryngoscopy or tracheal intubation. The area over the LD-SBF wave and under a tangent line drawn between the drop point and recovery point (fig. 1) was measured as SVmR area by the unit of pixel.

DATA ANALYSIS

Mean arterial pressure (MAP) was calculated as diastolic arterial pressure and one-third pulse pressure. The change in MAP was measured as the difference between MAP recorded before laryngoscopy-1 and maximum MAP in the period during laryngoscopy-1 to 2 min after this. In a similar manner, the change in MAP during intubation with laryngoscopy-2 was calculated using the arterial pressure value from before laryngoscopy-2 to 2 min after intubation. The change in HR in laryngoscopy-1 was determined as the difference between HR recorded before laryngoscopy-1 and maximum

HR during laryngoscopy-1 to 2 min after this. The change in HR in intubation with laryngoscopy-2 was calculated similarly.

Results are presented as mean (SD). Haemodynamic data within each group were analysed using a repeated measures analysis of variance, and differences between groups were analysed using the Student's *t* test. Changes in LD-SBF, SVmR-RR and SVmR area were assessed by the Wilcoxon signed rank test within each group, and the Mann–Whitney *U* test between groups. $P<0.05$ was considered significant.

Results

An inspiratory gasp provoked the SVmR in all patients before induction of anaesthesia; therefore, none was excluded. Patient age, weight and body mass index in the McC–Mac group were 34.2 (range 21–47) yr, 54.9 (SD 10.3) kg and 22.3 (2.7), respectively. Those in the Mac–McC group were 34.5 (26–50) yr, 55.3 (6.9) kg and 22.9 (2.6). There were no significant differences between the groups in patient characteristics. No patient had a difficult airway. A clear view of the vocal cords (grade I view defined by Cormack and Lehane) was obtained with both the Macintosh and McCoy blades in each patient.

Figure 2 shows simultaneous recording of tonometry arterial pressure (TAP) and LD-SBF level of representative patients from the McC–Mac group (top) and the Mac–McC group (bottom). Table 1 lists the changes in LD-SBF level. The LD-SBF level increased after induction of anaesthesia in both groups. Laryngoscopy-1 and intubation with laryngoscopy-2 procedures significantly reduced the LD-SBF level in both groups ($P<0.01$). The LD-SBF level at 1 min after each procedure recovered to the level observed immediately before the procedure. There were no significant differences between the groups regarding changes in LD-SBF level.

MAGNITUDE OF THE SVMR AND HAEMODYNAMIC RESPONSES

There were no significant differences in SVmR-RR between the two groups (table 2). In each group, the SVmR-RR of laryngoscopy-1 also did not differ from that of intubation with laryngoscopy-2. There was no significant difference between the groups in

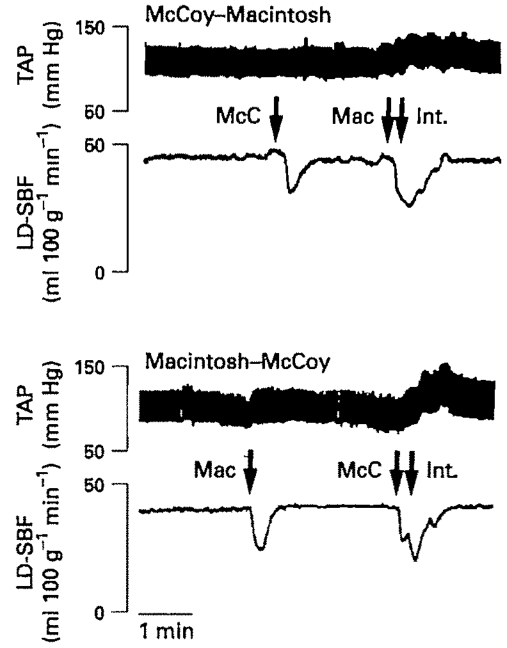

Figure 2 Representative records illustrating the relationship between tonometry arterial pressure (TAP) and skin blood flow on the laser-Doppler flowmeter (LD-SBF) (top: patient in the McCoy–Macintosh group; bottom: patient in the Macintosh–McCoy group). The arrows with "McC" and "Mac" indicate laryngoscopy with the McCoy and Macintosh blades, respectively. Int. = tracheal intubation.

SVmR area; however, SVmR area in intubation with laryngoscopy-2 was significantly greater than that in laryngoscopy-1 within each group ($P=0.01$ in the McC–Mac group; $P=0.005$ in the Mac–McC group). HR and MAP did not change during laryngoscopy-1, whereas intubation with laryngoscopy-2 significantly increased both HR ($P=0.006$ in the McC–Mac group; $P=0.008$ in the Mac–McC group) and MAP ($P=0.04$ in the McC–Mac group; $P=0.03$ in the Mac–McC group). However, haemodynamic changes were not significantly different between groups.

Discussion

We have demonstrated that both laryngoscopy and intubation provoked the skin vasomotor reflex (SVmR), nociceptive stimulation by intubation with laryngoscopy had a larger magnitude than that by laryngoscopy alone and the magnitude of nociception caused by laryngoscopy, which was measured by the SVmR, did not differ whether the Macintosh or McCoy blade was used.

The SVmR involves complex mechanisms, that is afferent, central and efferent pathways.[9–13] An inspiratory gasp and various sensory stimuli are representative afferent inputs for the SVmR. During laryngoscopy and intubation, nociceptive signals are generated by elevation of the epiglottis with the laryngoscope and by insertion of the tube into the trachea. The signals are conducted to the brain through the glossopharyngeal nerve and the vagus. The central polysynaptic pathways of the SVmR have not yet been clarified. The pressor response to laryngoscopy and intubation is mediated via sympathetic nerves.[20–22] The efferent pathway of the SVmR caused by any afferent stimulus has also been reported to be composed of sympathetic nerve fibres.[9–13]

The anaesthesia techniques among the studies of circulatory responses to laryngoscopy and intubation have varied widely.[1–7,20–22] As changes in HR and MAP in our study did not differ markedly from the haemodynamic changes in non-treated groups in previous reports,[1–7] our anaesthetic technique was adequate for tracheal intubation. We found recently that laryngoscopy and intubation provoked the SVmR during induction of anaesthesia with both nitrous oxide–sevoflurane and fentanyl–propofol (unpublished observation). Sympathetic vasomotor activity may exert potent control of vascular resistance in the skin and skin tissues which serve as potentially major targets for powerful sympathetic homeostatic reflexes.[23] Sympathetic discharge patterns recorded simultaneously from different skin nerves show striking similarities.[24] Our findings suggest that the SVmR contributes, at least in part, to the haemodynamic responses during laryngoscopy and intubation. There are few reports of the SVmR during general anaesthesia. Further studies are necessary to clarify if there is an intimate relationship between the SVmR and haemodynamic responses during laryngoscopy and intubation.

The SVmR is an indirect method of assessment of the sympathetically mediated reflex. It has not yet been confirmed if a linear, quantitative correlation exists between the magnitude of the SVmR and skin sympathetic nerve activity. However, the relationship between the SVmR-RR induced by transcutaneous electrical stimulation of the ulnar nerve and the current intensity of the stimulus showed a significant correlation during nitrous oxide–sevoflurane anaesthesia (unpublished observation). Evaluation of the SVmR may have the potential to be a non-invasive indicator of nociception during general anaesthesia.

We found that combined laryngoscopy and intubation provided larger nociceptive stimulation compared with laryngoscopy alone. The durations of the two procedures should not account for the difference because the elimination half-lives of fentanyl and midazolam are reported to be 3.6 h[25] and 3.8 h,[26] respectively. Stoelting reported that prolonged laryngoscopy increased mean arterial pressure with time during the first 45 s.[27] This report and our findings suggest that the duration of nociceptive stimulation itself plays an important role in the magnitude of SVmR area and haemodynamic changes during laryngoscopy and intubation.

McCoy and colleagues demonstrated that the circulatory responses to laryngoscopy were less marked with the McCoy blade compared with the Macintosh blade.[14,15] In our study there were no significant differences in the magnitude of the SVmR and haemodynamic changes induced by the use of either blade. To expose the larynx, the tip of the blade is inserted into the epiglottic vallecula and moved up towards the mandible. These procedures are common to each blade. Regardless of the blade style, a 3-s view of the larynx caused the SVmR. Cook and Turky reported that the McCoy blade in the neutral position provided a poorer view of the larynx and needed "levering" to obtain the view similar to that provided by the Macintosh blade.[28] This report and our findings suggest that the magnitude of nociception caused by elevation of the epiglottis itself does not differ between the two blades for patients with a normal body size and anatomical structure of the upper airway.

Effect of felodipine on renal function and vasoactive hormones in infrarenal aortic surgery

L. DE LASSON, H. E. HANSEN, B. JUHL, W. P. PAASKE AND E. B. PEDERSEN

Summary

We have examined the possible renoprotective effect of felodipine 5 mg orally, given daily for 5 days before operation, in 29 patients undergoing elective infrarenal aortic surgery in a randomized, blinded and placebo-controlled study. Effective renal plasma flow (ERPF), glomerular filtration rate (GFR), urine output, fractional sodium clearance and plasma concentrations of angiotensin II, aldosterone, arginine vasopressin and atrial natriuretic peptide did not differ between the felodipine and placebo groups. ERPF and GFR were not reduced after operation in the placebo group. In the felodipine group, GFR was higher 24 h after operation compared with before operation. We conclude that increased GFR in the felodipine group, measured 24 h after operation, may indicate a beneficial effect of felodipine but in the present context this was not clinically important. Felodipine had no significant effect on vasoactive hormones. (*Br. J. Anaesth.* 1997; **79**: 719–725).

Key words
Calcium channel block, felodipine. Kidney, blood flow. Surgery, vascular. Hormones, vasoactive.

It is not known why effective renal plasma flow (ERPF) and glomerular filtration rate (GFR) decrease after cross-clamping of the infrarenal aorta[1] [2] or why reduced renal blood flow is associated with decreased postoperative creatinine clearance.[3] The cause of this renal impairment is probably multifactorial.

Calcium antagonists cause vasodilatation at raised tone in afferent renal arterioles and ameliorate experimental renal ischaemia.[4] Felodipine is a dihydropyridine calcium antagonist, characterized by high vascular selectivity, which causes a reduction in systemic vascular resistance, and has no adverse effects on myocardial contractility or conduction.

In this prospective, randomized, placebo-controlled study, we have examined if treatment with felodipine for 5 days before operation influenced ERPF, GFR, fractional excretion of sodium and potassium, osmolar clearance or vasoactive hormones in elective surgery for infrarenal atherosclerosis.

Patients and methods

We studied 29 patients with aorto-iliac occlusive arterial disease undergoing elective aorto-biliac or aorto-bifemoral graft implantation. The study was approved by the Danish National Health Board and the local Ethics Committee, and all patients gave written informed consent. One of the authors (L. de L.) anaesthetized all patients.

Patients were invited to participate in the study if kidney function was normal after diethyltriamine-pentaacetic acid (DTPA) renography. Exclusion criteria were: age more than 70 yr; myocardial infarction within the past year; cardiovascular symptoms or receiving medications; unstable angina or stable angina with congestive heart failure; symptomatic cerebrovascular disease; diabetes mellitus; diastolic arterial pressure ≥100 mm Hg; cardiac valvular stenosis with haemodynamic implications; systemic therapy with bronchodilators or steroids; or treatment with a calcium antagonist or an angiotensin converting enzyme inhibitor.

Patients were excluded during the study if they experienced postoperative pain requiring replacement of extradural catheter, loss of more than 50% of estimated blood volume or there were technical failures during sampling.

FELODIPINE TREATMENT AND SIDE EFFECTS

The randomization and preparation of felodipine extended release tablets (5 mg) and placebo were undertaken by Astra AB, Sweden. This dose was chosen because patients were normotensive. Felodipine treatment was started 5 days before operation, after a clearance test. The day before operation, patients were asked if they had any complaints relating to felodipine treatment including, ankle oedema, headache, flushing, palpitations, dizziness or tiredness. All patients received their last felodipine dose 1.5–2.5 h before anaesthesia.

RENAL HAEMODYNAMICS, HORMONES AND ELECTROLYTES

ERPF and GFR were measured before treatment with felodipine or placebo and twice after operation (when patients were haemodynamically stable, 1 h after operation and 24 h after operation). On these three occasions, plasma concentrations of angiotensin II, aldosterone, arginine vasopressin (AVP) and atrial natriuretic peptide (ANP) were measured. On the same three occasions, plasma concentrations of electrolytes were analysed for calculation of clearances of sodium, potassium and water, and osmolality was also measured. Plasma concentrations of felodipine were measured 1 and 24 h after operation.

ANAESTHESIA AND ANALGESIA

Premedication comprised diazepam 10–15 mg orally, 1 h before anaesthesia. An extradural catheter was inserted at T10–11 or one segment above, and 0.5% plain bupivacaine 6–10 ml was administered as a bolus followed by an infusion of 5 ml h^{-1}. General anaesthesia was induced with midazolam 2.5–5 mg, fentanyl 3–5 $\mu g\ kg^{-1}$ and thiopentone 50–250 mg. The trachea was intubated after administration of pancuronium 1 mg and suxamethonium 75–100 mg i.v. A bolus dose of pancuronium 6–8 mg was given to achieve neuromuscular block. Anaesthesia was maintained with 0.4–1.0% halothane. Signs of patient discomfort during surgery (increased heart rate or arterial pressure, dilated pupils or sweating) were treated with extradural bupivacaine 3 ml at incision and later with alfentanil 0.5 mg i.v. Hypotension was treated with a bolus dose of ephedrine 2–5 mg or noradrenaline 2–5 μg (if systemic vascular resistance was <800 dyn s cm^{-5}) while corrective measures were taken in terms of fluid infusion and adjustment of the level of anaesthesia. Dopamine 3 $\mu g\ kg^{-1}\ min^{-1}$ was administered after insertion of the pulmonary artery catheter until 06:00 the next morning. The trachea was extubated at the end of operation. After operation, extradural infusion continued with 0.17% plain bupivacaine 5–8 ml h^{-1} until midnight. In the intensive care unit, extradural morphine 3–4 mg was injected every 6–8 h. Diuretics were not administered during the study. Droperidol bolus doses of 1.25 mg were used as an antiemetic.

MONITORING

The ECG (leads II and V5) was monitored continuously. A 5-French thermodilution pulmonary artery catheter was inserted via the right internal jugular vein and a nasopharyngeal temperature probe, nasogastric tube and urinary bladder catheter inserted. During operation, systemic mean arterial pressure (MAP), pulmonary artery mean pressure (PAMP), heart rate (HR) and central venous pressure (CVP) were displayed continuously. Pulmonary artery wedge pressure (PAWP) and cardiac output were measured as required, and cardiac index (CI), stroke volume index (SVI) and systemic vascular resistance (SVR) were calculated. Haemodynamic observations were recorded five times during operation in all patients (before skin incision; before aortic cross-clamping; 5 min after clamping; at completion of vascular anastomoses; and at the end of operation) and at the same times as the postoperative clearance measurements.

Systemic arterial blood samples were analysed to ensure normocapnic ventilation and adequate oxygenation during operation.

FLUID TREATMENT

Before skin incision, fluid was administered to compensate for vasodilatation caused by extradural and general anaesthesia: Dextran 70, 60 mg ml^{-1} with isotonic sodium chloride 300–400 ml m^{-2} body surface area and an equal volume of isotonic saline. During operation, isotonic saline was infused to compensate for evaporation and third space loss: 600 ml m^{-2}, 400 ml m^{-2} and 200 ml m^{-2} in the first, second and third hours of operation, respectively. In addition, isotonic saline was given in a volume equivalent to the volume of urine produced during the previous hour of operation. Blood loss was compensated for by Dextran 70 up to a maximum dose of 1.5 g kg^{-1} and then human albumin was given. If packed cell volume was less than 0.28, SAG-M blood was transfused during and after operation.

After operation, crystalloid was infused at a rate of 60 ml $m^{-2}\ h^{-1}$ until the next morning at 06:00 and at 120 ml $m^{-2}\ h^{-1}$ thereafter. Human albumin was given if hypovolaemia occurred (hypotension at low PAWP and normal SVR).

LABORATORY ANALYSES

GFR and ERPF were measured by the constant infusion clearance method.[5] The reference substances were ^{125}I-iothalamate and ^{131}I-hippuran in the first 10 patients and ^{51}Cr-EDTA and ^{125}I-hippuran, respectively, in the other patients, because of administrative changes. The same method was used in each patient.

Angiotensin II was measured by radioimmunoassay using a modification of the method described by Kappelgaard, Nielsen and Giese.[6] The minimum detection level in plasma was 2 pmol $litre^{-1}$. Coefficients of variations were 12% (inter-assay) and 8% (intra-assay). Aldosterone was measured by a slight modification of a method described previously.[7] The minimum detection level was 42 pmol $litre^{-1}$. Coefficients of variation were 13% (inter-assay) and 9% (intra-assay). Atrial natriuretic peptide was measured by radioimmunoassay as described previously.[8] The minimum detection level in plasma was 0.5 pmol $litre^{-1}$. Coefficients of variation were 12% (inter-assay) and 10% (intra-assay). Arginine vasopressin was measured radioimmunologically by a slight modification of a method described previously.[9] The minimum detection level was 0.5 pmol $litre^{-1}$. Coefficients of variation were 13% (inter-assay) and 9%

(intra-assay). Plasma felodipine assays were conducted by Astra AB, Sweden. Clearance data were standardized to a body surface area of 1.73 m^2.

STATISTICAL ANALYSIS

In a previous study with similar patients,[11] there were 12 patients in each group and the SD for preoperative GFR was 17.5 ml min^{-1}. With a minimum relevant difference between means of 26.3 ml min^{-1}, $\alpha=0.05$ and $\beta=0.10$, the number of patients required in each group was calculated as nine. The Mann–Whitney and non-parametric two-way analysis of variance tests were used (significance level 0.05). Intra-group differences were examined by the Wilcoxon test (significance level 0.02). Unless otherwise specified, results are presented as median (interquartile ranges).

Results

There were 14 and 15 patients in the felodipine and placebo groups, respectively. Patients were not receiving cardiorespiratory drugs, except for one patient in the felodipine group who was treated with a diuretic for hypertension; this patient was not excluded.

Side effects of felodipine included headache in one patient, and another was exceptionally tired. One other patient reported palpitations, and one had flushing of the face and oedema of the ankles and fingers. In the placebo group, one patient confessed to all side effects. One patient complained of headache and one suffered from dizziness.

Table 1 Patient characteristics (values are median (range)). *Mean arterial pressure=1/3(systolic arterial pressure−diastolic arterial pressure)+diastolic arterial pressure

	Felodipine group	Placebo group
Sex (F/M)	5/6	9/3
Age (yr)	65 (46–69)	60 (47–68)
Height (m)	1.68 (1.52–1.80)	1.66 (1.54–1.77)
Weight (kg)	66 (53–79)	64.5 (54–82)
ASA II	11	12
Arterial pressure (mm Hg)*	95	94

Table 2 Duration of operation (OP), aortic cross-clamping time (ACC), and blood loss (values are median (interquartiles))

	Felodipine group	Placebo group
OP (min)	108 (99–158)	125 (116–150)
ACC (min)	19 (15–25)	20 (17–30)
Blood loss (ml)	1150 (550–1600)	1000 (544–1425)

Three patients were excluded from each group. In the felodipine group one patient developed influenza after randomization and the operation was cancelled; one patient lost excessive quantities of blood during operation; and the third patient had the extradural catheter replaced. In the placebo group, one patient lost excessive quantities of blood, one had replacement of the extradural catheter and one was excluded because of technical problems. Table 1 describes the 23 patients who completed the study. Age, weight and height in the two groups were well matched.

There were no major complications during or after operation. In the felodipine group, one patient developed sinus bradycardia on day 4 after operation. One patient developed a silent subendocardial infarction during the night before operation. She was discharged home 8 days after operation in good health. One patient in the placebo group had atrial fibrillation.

Duration of operation, aortic clamping time and intraoperative blood loss (table 2) were similar in the two groups. The number of patients who received bolus doses of ephedrine/noradrenaline was 6/4 in the felodipine group and 7/7 in the placebo group. Hypotension (SVR 430–813 dyn s cm^{-5}) on the night after operation was treated with infusion of noradrenaline in two patients in the felodipine group and in four patients in the placebo group. Two patients in the placebo group required infusion of noradrenaline during the last postoperative clearance measurement.

CENTRAL HAEMODYNAMICS

Mean preoperative arterial pressure (table 1) was unchanged in the felodipine group. There was no difference between the groups in central haemodynamic variables during operation (PAWP, CVP, HR, MAP, PAMP, CI, SVI and SVR). There was a time–treatment interaction for CVP and PAMP ($P=0.033$ and 0.035). CVP, PAMP and PAW are shown in figure 1 and HR, MAP and CI in table 3. We did not estimate intra-group differences as haemodynamic variations

Table 3 Peroperative heart rate (HR), mean arterial pressure (MAP), and cardiac index (CI) (median (interquartiles)). a=before incision, b=before clamping, c=5 min after clamping, d=after completion of the vascular anastomoses, e=end of operation. There were no inter-group differences

are expected during major vascular procedures.

RENAL HAEMODYNAMICS

The two groups did not differ in ERPF and there was no time–treatment interaction. In both groups ERPF was increased at the first postoperative clearance test (felodipine $P=0.004$; placebo $P=0.002$) compared with the preoperative level (fig. 2). GFR (fig. 2) did not differ in the two groups, there was a

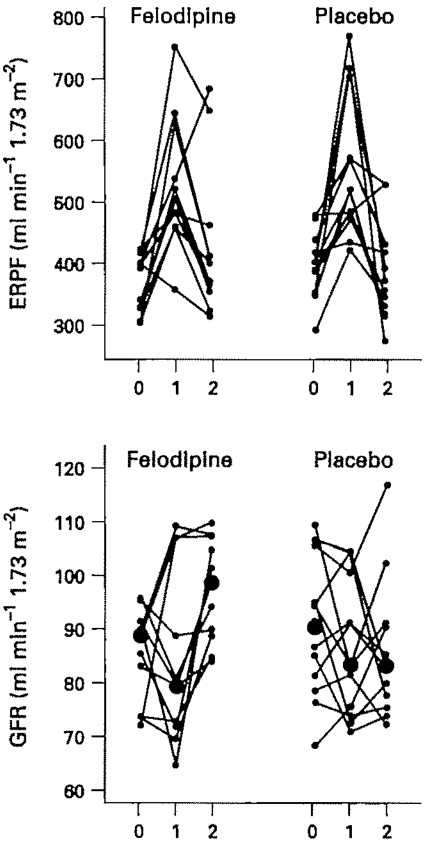

Figure 2 Effective renal plasma flow (ERPF) and glomerular filtration rate (GFR) (means of 2–3 measurements) in the felodipine and placebo groups at: 0=preoperative measurement, 1=first postoperative measurement (haemodynamic stability 1 h after operation), 2=second postoperative measurement (24 h after operation). ERPF: there was no difference between groups, but ERPF was increased at the first postoperative clearance test in both groups compared with preoperative levels. GFR: there was no difference between groups but there was a time–treatment interaction, and GFR was increased 24 h after operation in the felodipine group compared with preoperative values. ●=Median value.

time–treatment interaction (P=0.049) and GFR was increased 24 h after operation in the felodipine group compared with preoperative values (P=0.016). The two groups did not differ in filtration fraction, and there was no time–treatment interaction. In both groups the filtration fraction was lower at the first postoperative clearance test than at the preoperative test.

WATER AND ELECTROLYTE CLEARANCE

Urine output was similar in the two groups: 310 (160–560) ml in the felodipine group compared with 490 (236–950) ml in the placebo group during operation, and 1815 (1494–2270) ml in the felodipine group and 2023 (1438–2385) ml in the placebo group until the next morning.

Fractional sodium excretion, fractional potassium excretion and osmolar clearance did not differ between the two groups, and there was no time–treatment interaction. Intra-group differences are shown in table 4. Free water clearance did not differ between groups, but there was a time–treatment interaction (P=0.027). Intra-group differences are shown in table 4.

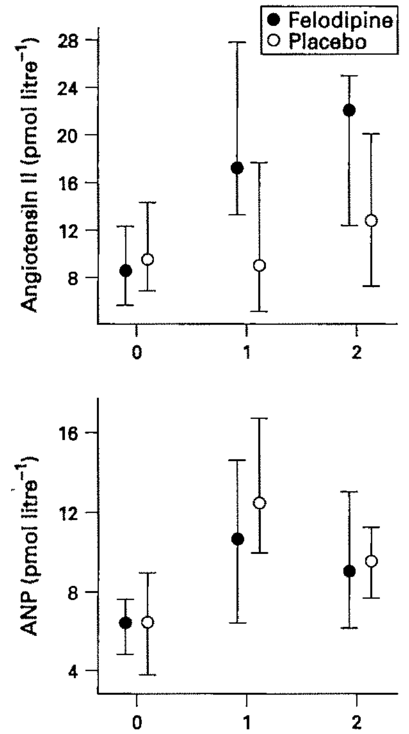

Figure 3 Angiotensin II and atrial natriuretic peptide concentrations (median and interquartiles) in the felodipine and placebo groups. 0= Preoperative measurement, 1=first postoperative measurement (haemodynamically stable, 1 h after operation), 2=second postoperative measurement (24 h after operation). Angiotensin II: there were no inter-group differences but angiotensin II concentrations were increased in the felodipine group at both postoperative clearance tests. ANP: there were no inter-group difference but ANP concentrations were increased at both postoperative clearance tests in both groups.

VASOACTIVE HORMONES

There were no group differences or time–treatment interactions for angiotensin II, aldosterone, atrial natriuretic peptide or vasopressin concentrations. In the felodipine group, angiotensin II was increased at both postoperative clearance tests compared with preoperative values, and ANP was increased in both groups for both tests after operation compared with preoperative values (fig. 3). Aldosterone concentrations were increased to three times preoperative levels at the first postoperative clearance test but returned to preoperative values after 24 h (table 5). Vasopressin concentrations were increased at the first postoperative clearance test and within a very broad range.

PLASMA CONCENTRATIONS OF FELODIPINE

Plasma concentrations of felodipine were 1.04 (0.82–1.63) nmol litre^{-1}, 1 h after operation and 0.30 (0.24–0.43) nmol litre^{-1}, 24 h after operation. The increase in GFR 24 h after operation compared with preoperative values did not correlate with felodipine concentrations.

Discussion

Felodipine did not improve postoperative renal function compared with placebo, and ERPF and GFR were not reduced in the placebo group. The increased GFR, 24 h after operation in the felodipine group, may indicate a beneficial effect of felodipine but in the present context it was not clinically important. Using the same clearance method, Gamulin and colleagues[1 2] demonstrated intraoperative reduction in renal blood flow and GFR after infrarenal aortic clamping. We undertook a postoperative study as it was not possible to maintain stable central and renal haemodynamics during surgery; these are necessary to achieve valid results.

The plasma concentrations of felodipine were less than the therapeutic level for antihypertensive treatment, the lower level being 2.5 nmol litre^{-1}.[10] To our knowledge the therapeutic plasma concentration for prevention of renal ischaemic damage is unknown.

Ours is the first randomized, placebo-controlled study of the renal effects of administration of a calcium antagonist in abdominal aortic surgery. Our results did not establish any benefit from treatment with low-dose felodipine, but the number of patients was small and there was a risk of a type II error. Our results did not excluded the possibility that felodipine may be beneficial in patients with a higher risk of reduced renal function after operation or that felodipine may be beneficial at higher plasma concentrations. The use of dopamine and high filling pressures may have prevented postoperative deterioration in renal function and therefore masked any effect of felodipine.

There was a difference between the groups in administration of vasoconstrictors. The increased ERPF at the first postoperative clearance test in both groups can be attributed to dopamine[11] as the effect of vasoconstrictors administered during operation had disappeared at this stage. ERPF measured 24 h after operation was similar to preoperative values, even during treatment with felodipine. ERPF values in the placebo group indicated neither renal vascular vasoconstriction nor vasodilatation at this stage.

Urine output and fractional excretion of sodium did not differ between the groups. Felodipine has natriuretic and diuretic effects immediately after single dose administration but these effects are less pronounced after days of drug administration.[12, 13]

Patients had an excellent outcome. Complications were minor in the context of postoperative morbidity after major vascular surgery.[14, 15] Patients in our study were a selected group without symptomatic coronary atherosclerosis. The complication rate was the same as in the treatment group in our previous study,[11] which compared the effect of dopamine 3 μg kg^{-1} min^{-1} with placebo in a similar population with the same anaesthetic and operative procedures. The conclusion of that study was that low-dose dopamine relieved cardiovascular depression caused by combined extensive thoracic extradural block and general anaesthesia, and therefore an inotropic adjuvant should accompany this anaesthetic technique.

Felodipine was tolerated well, and side effects were the same in the placebo group. In hypertensive patients, the expected cardiovascular effect of felodipine is a reduction in arterial pressure because of lower peripheral vascular resistance and a higher cardiac index.[16] During operation, mean arterial pressure, heart rate, cardiac index and systemic vascular resistance index were the same in the two groups. Any possible effect of felodipine was not discernible in the presence of operative stress, anaesthesia and low-dose dopamine. The reason for the slightly higher central venous arterial pressure and mean pulmonary artery pressure in the felodipine group is not obvious. Cardiac index did not differ between the groups which indicates that there was no severe depression of ventricular function. Pulmonary artery wedge pressure showed the same trend but was not significant. One would expect concentrations of atrial natriuretic peptide to differ between groups if the trend in these pressures represented imminent heart failure.

Administration of a dihydropyridine calcium antagonist was accompanied by increased plasma concentrations of angiotensin II and unchanged plasma aldosterone concentrations.[12, 17] In this study, aldosterone was increased after operation as expected, but there was no difference between the groups. Twenty-four hours after operation aldosterone concentrations were the same as those measured before operation which may indicate that fluid administration was adequate. Perhaps ANP was increased after operation in both groups as an indication of generous fluid treatment but the levels were moderate compared with those found in heart failure.[18, 19] Our observations mirror the modulating balance between the vasoconstrictor/sodium-retaining effect of the renin–angiotensin–aldosterone system and the vasodilating/diuretic–natriuretic effects of the natriuretic peptides.[20] AVP increased after operation, as observed previously in patients treated with low-dose dopamine,[11] whereas AVP was not increased after operation in the placebo group.[11] Nausea and opioids are well known triggers of AVP release,[21, 22] but the physiological significance of this finding is not obvious.

Acknowledgements

The study was supported by a grant from the Danish Medical Research Council. Astra AB, Sweden supported the study financially, handled the randomization, blinding and preparation of drug and analysed the plasma felodipine samples. We thank Dr Michael Rehling, Department of Nuclear Medicine, for DTPA renographies.

Effects of temperature on phrenic nerve and diaphragmatic function during cardiac surgery

G. H. MILLS, Z. P. KHAN, J. MOXHAM, J. DESAI, A. FORSYTH AND J. PONTE

Summary

We have studied the effects of whole body cooling on phrenic nerve and diaphragmatic function in 26 patients using magnetic stimulation of the phrenic nerves with a pair of Magstim 200 HP stimulator coils during cardiopulmonary bypass. The diaphragmatic electromyogram in response to magnetic pulses was recorded with needle electrodes at two temperatures, approximately 31 °C (cold) and approximately 36 °C (warm) during the cooling or rewarming phase of hypothermic cardiopulmonary bypass. This 5-°C temperature change was associated with clear changes in the evoked electromyographical response of the diaphragm. Median latency between stimulus and electromyographic response was 10.1 (range 8.0–11.8) ms during cold and 8.3 (5.9–10.2) ms during warm stimulation ($P<0.001$). Median duration of the muscle compound action potential was prolonged and its amplitude reduced in cold compared with warm stimulations ($P<0.01$). These effects were enhanced by application of ice slush to the heart. We conclude that diaphragmatic function may be affected by mild hypothermia after cardiac surgery. (*Br. J. Anaesth.* 1997; **79**: 726–732).

Key words
Temperature, effect. Heart, cardiopulmonary bypass. Surgery, cardiovascular. Muscle skeletal, diaphragm.

Diaphragmatic dysfunction and phrenic nerve injury are well recognized complications of cardiac surgery that often require prolonged ventilatory support.[1] One possible cause of diaphragmatic dysfunction is exposure of the phrenic nerves to ice slush during cardiopulmonary bypass. Moderate cooling of the phrenic nerves or the diaphragm in animals[2–4] has been shown to slow the velocity of nerve conduction and to prolong the muscle action potential, effects also observed in other skeletal muscle groups.[5–8] Exposure of the phrenic nerve to ice slush has also been studied in animals and shown to cause phrenic nerve conduction block proportional to exposure time,[3 4 9] but similar human studies are lacking. The technique of magnetic stimulation of the diaphragm[10 11] is well suited to study the effects of local cooling on phrenic nerve and diaphragm function during cardiopulmonary bypass, causing minimal interference with the course of surgery.

In the absence of gross cardiac or diaphragmatic dysfunction, many centres are aiming to reduce the time of postoperative ventilation in cardiac surgery, usually extubating the trachea of patients within 4 h of surgery. It is believed generally, however, that when patients are hypothermic (<36 °C) on arrival in recovery, mechanical ventilation should be maintained until a core temperature of 37 °C is reached, thus imposing a considerable limitation to the "fast tracking" of these patients. There is, however, no direct evidence that the function of the human diaphragm is impaired by mild hypothermia.

In this study our aim was to document the effects of moderate whole body hypothermia (31–32 °C) and the use of ice slush around the heart on diaphragmatic function.

Patients and methods

The study was approved by the King's Healthcare Ethics Committee and informed consent was obtained from 26 consecutive patients (seven females) referred for coronary artery surgery. Patients with neurological conditions or diabetes were excluded. Morphometric data and cardiopulmonary bypass times are shown in table 1.

ANAESTHETIC MANAGEMENT

Patients were premedicated with temazepam 30 mg, ranitidine 150 mg, papaveretum 11.5 mg and hyoscine 0.3 mg, and anaesthesia was induced with a bolus dose of propofol 50–100 mg and fentanyl 0.5 mg. Anaesthesia was maintained with an infusion of propofol at a rate of 5–10 mg kg^{-1} h^{-1} throughout, and another bolus of fentanyl 0.5 mg before sternotomy. Intubation of the trachea was facilitated by the use of a single dose of either vecuronium 0.08 mg kg^{-1} (20 patients) or suxamethonium 1 mg kg^{-1} (six patients) and no

Cold–warm (min)	22.6 (10.8)

further doses of neuromuscular blocking agents were given throughout surgery.

SURGICAL MANAGEMENT

All patients had three or four coronary grafts performed. The two mammary arteries were dissected in all patients. During cardiopulmonary bypass, all patients were cooled actively to a nasopharyngeal temperature of 32 °C during suturing of the distal ends of the grafts and then warmed to 38 °C before restoring normal circulation. Preservation of the myocardium was achieved with intermittent perfusion of the coronary system via the root of the aorta with blood containing (mmol litre^{-1}): KCl 16, MgCl 16 and procaine 1, at 10–11 °C. Sixteen of the 26 patients also had one single application of ice slush around the heart, without insulating pads. Durations of cardiopulmonary bypass and clamping of the aortic root were noted for all patients (table 1). No patient was receiving inotropes during or before the periods of testing diaphragmatic responses to phrenic stimulation.

RECORDINGS OF DIAPHRAGMATIC EVOKED EMG SIGNALS

After sternotomy, fine needle electrodes were inserted into the thickness of the anterior quadrant of the left hemidiaphragm, approximately 5 cm from the rib insertions, parallel to the muscle fibres. A fine needle temperature sensor was also inserted into the diaphragm in the vicinity of the electrodes. The left hemidiaphragm was chosen because the highest incidence of phrenic dysfunction has been reported on this side.[12–14] The phrenic nerves were stimulated with a 43-mm mean diameter double magnetic coil placed on the anterolateral surface of the neck over the left phrenic nerve. Two double coils were used when both phrenic nerves were stimulated simultaneously.[10 11] Each double coil was powered by a Magstim 200 HP stimulator (Magstim Company, Whitland, Dyfed, Wales). Five consecutive supramaximal stimulations at 15-s intervals, at 100% of maximum stimulator power, were performed at each temperature and the results averaged. The magnetic technique was selected because of the ease with which the phrenic nerve can be stimulated reproducibly. Compared with electrical stimulation, magnetic stimulation is more effective in achieving supramaximal stimulation of the phrenic nerve and is far less sensitive to positioning of the electrodes.[10] The output of the magnetic stimulator was set to maximum in this study, ensuring reliable supramaximal stimulation of the phrenic nerves, as documented in a previous study using the same device.[10] The diaphragmatic evoked electromyograms (EMG) were recorded via sterilized needle electrodes linked to a Magstim Neurosign 2000 amplifier designed for use with patients. The analogue EMG signal was converted to digital form on a National Instruments 12 bit NB-MIO 16 board (National Instruments, Austin, TX, USA) and stored in a MacIntosh 650 Quadra computer (Apple Computer Company, Cupertino, CA, USA). The EMG signal was sampled at 10 kHz and processed on-line using a program developed on LabView 2.2 software (National Instruments, Austin, TX, USA). The magnetic pulse stimulation of the phrenic nerves consistently evoked a compound action potential in the EMG tracing recorded from the diaphragm by the needle electrodes (fig. 1).

The electromyographical measurements were made in all 26 patients: (a) during cardiopulmonary bypass, before re-warming, while the diaphragmatic temperature was approximately 31 °C; and (b) after whole body rewarming when the diaphragmatic temperature was approximately 36 °C. In four of the 16 patients who received ice slush on the heart, an additional set of 13 measurements was obtained (c), the first just before applying the ice slush, the subsequent 11 measurements at 5-min intervals for 55 min and the last measurement at the latest possible time before closing the chest. In six patients whose nasopharyngeal temperatures remained at or above 36 °C at the time of opening the chest and did not receive ice slush, additional electromyographical measurements were made (d) shortly after sternotomy and (e) during the active cooling period at the beginning of cardiopulmonary bypass.

Most of the temperature related data were obtained at the transition from cold to warm occurring at the end of cardiopulmonary bypass, rather than at the transition from warm to cold at the beginning of bypass, for two reasons: first, to allow more time for possible residual effects of the neuromuscular blocking agent (used only to facilitate intubation of the trachea) to dissipate and for stable plasma concentrations of propofol to be achieved; second, most patients had a nasopharyngeal temperature of less than 36 °C at induction of anaesthesia and by the time the chest was opened, most had cooled passively to 34–35 °C. In six subjects whose nasopharyngeal temperature had not decreased to less than 36 °C when the chest was opened, recordings (d) and (e) were also made. These additional data allowed us to observe if the changes occurring during cooling were similar to those observed during re-warming.

OTHER MEASUREMENTS

Temperature measurements were made in the nasopharynx with a standard thermocouple sensor and in the diaphragm with a fine myocardial needle thermocouple sensor (Ellab A/S, Roedovre, Denmark) placed close to the EMG electrodes. At the time of stimulation, diaphragmatic temperature might differ from nasopharyngeal temperature by 0.5–1 °C. It was diaphragmatic temperature, however, that was noted for the purpose of the study although nasopharyngeal temperature was used as a guide for perfusion.

Arterial blood pH, $P\text{CO}_2$ and $P\text{O}_2$, and plasma concentrations of sodium, potassium and calcium were measured at the time of phrenic nerve stimulation using a self-calibrating Ciba-Corning 288 Blood Gas System, available in the same room. Plasma concentrations of propofol were measured when the electrophysiological tests (a) and (b) were performed.

Gastric pressures (Pgas cm H_2O) were measured after simultaneous stimulation of both phrenic nerves in four patients. A 100-cm balloon catheter (PK Morgan, Rainham, Kent, UK) was passed through the nose into the stomach at the start of operation with the aid of a lubricated size 7 uncuffed and uncut red rubber nasotracheal tube. Recordings were obtained with regularly tested[15] Validyne MP45 pressure transducers and amplifiers (Validyne Corporation, Northridge, CA, USA). The mean values of peak amplitudes of four deflections were calculated at two temperatures. Oesophageal pressure recordings were not made during surgery because the chest was open.

Video recordings of the diaphragm during the five phrenic stimulations at each temperature were made in two patients. These were edited subsequently to visually compare the cold and warm twitch responses in quick succession.

ANALYSIS OF DATA

An example of an evoked compound action potential of the diaphragm obtained with the needle electrodes is shown in figure 1. Three values were derived from the evoked EMG trace, as indicated in figure 1: (a) "latency" or time elapsed between the magnetic stimulus artefact and the first deflection of the EMG trace (ms); (b) "duration" or time elapsed between the first deflection and the second peak of the compound action potential (ms); and (c) "amplitude" or magnitude (mV) of the difference between the positive and negative peak deflections of the compound action potential. Absolute amplitude values (mV) were very variable from patient to patient because of the relative positioning of the recording needle electrodes. Therefore, for the tables and for comparison purposes, we decided to express all amplitude values as relative changes with respect to the first set of measurements obtained during the cold period which were taken as 100. In the six patients in whom the warm to cold transition was also studied, the warm value was set to 100 for that set of measurements only. Latency, duration and amplitude were compared between cold (approximately 31 °C, diaphragmatic temperature) and warm (approximately 36 °C) conditions using the Wilcoxon signed rank test. A non-parametric test was used to process these data because of the obvious skew in the distribution. These comparisons were obtained independently for the two subsets of patients who received and who did not receive ice slush. Based on previous studies, the upper limit of normal for latency was taken as 9.5 ms.[16]

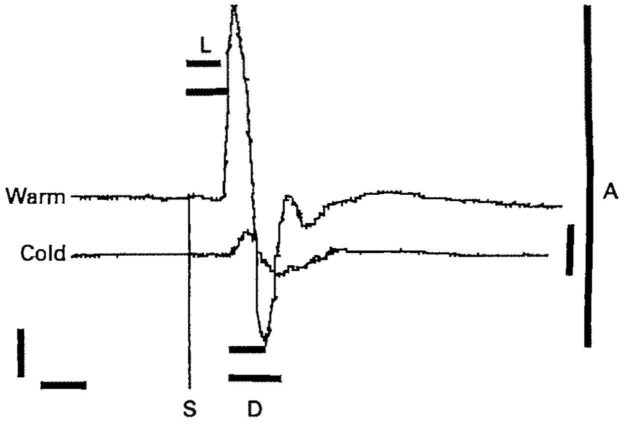

Figure 1 Representative example of two evoked compound action potentials recorded directly from the left diaphragm using needle electrodes, in response to pulses of magnetic stimulation to the left phrenic nerve in one patient. Recordings were made at two diaphragmatic temperatures: first, cold (approximately 31 °C) and 12 min later, warm (approximately 36 °C). S=Stimulus artefact; L=latency (the bars represent the latencies between stimulus and the first deflection in "cold" and "warm" conditions); D=durations between the first deflection and the peak on the second wave; and A=amplitudes of the "warm" and "cold" conditions. On the bottom lefthand corner, horizontal bar=10 ms and vertical bar=0.2 mV.

The influence of possible changes in other factors which might have occurred simultaneously with the change in temperature was also tested. Plasma concentrations of propofol, sodium (Na^+), potassium (K^+) and calcium (Ca^{++}), and arterial blood-gas tensions were compared between cold and warm periods for each of these factors using the paired t test. Duration of cardiopulmonary bypass and aortic cross-clamping time were recorded.

Results

TEMPERATURE OF THE DIAPHRAGM

Before starting warming at the end of cardiopulmonary bypass, mean diaphragmatic temperature was 31.3 (SD 1.87) °C when the cold set of measurements were obtained; nasopharyngeal temperature was at the target value of 32 °C. As the warm end-point of 38 °C in the nasopharynx was reached, mean diaphragmatic temperature was only 36.5 (1.44) °C when the second, warm set of measurements were obtained. This 1.5-°C difference between diaphragmatic and nasopharyngeal temperatures was only reduced slightly (<0.5 °C) in the course of the ensuing 5–10 min after the set of warm measurements were obtained and before cardiopulmonary bypass was discontinued. Thus a gradient of approximately 1 °C between diaphragmatic and nasopharyngeal temperatures was nearly always present at the end of bypass.

PLASMA VARIABLES, CARDIOPULMONARY BYPASS VARIABLES AND BODY TEMPERATURE CHANGES

Plasma concentrations of propofol (total range 0.54–5.33 μg ml^{-1}), Na^+ and Ca^{++}, and arterial blood-gas values did not differ (paired *t* test, except for pH where the Wilcoxon sign rank test was used) between the cold and warm test conditions. Only plasma K^+ concentration was significantly different in the two conditions ($P=0.03$), being higher during the warm condition by 0.28 mmol litre^{-1}.

CHANGES IN LATENCY, DURATION AND AMPLITUDE OF THE EVOKED DIAPHRAGMATIC EMG ASSOCIATED WITH CHANGES IN TEMPERATURE

An example of the effect of a change in temperature from 31 to 36 °C on the evoked muscle action potential in one patient is shown in figure 1. Data relating diaphragmatic evoked EMG latency, duration and amplitude to diaphragmatic temperature are summarized in table 2 for all patients and for two subgroups, those who did and those who did not receive ice slush. Comparisons between cold and warm conditions for all patients showed significant differences for the three variables; percentage changes in latency, duration and amplitude were −18, −14 and +99%, respectively.

Direct observation of the twitch contractions of the diaphragm in response to the magnetic pulses showed an obvious difference between the cold and warm testing conditions in all patients. The contraction was more vigorous and shorter in duration under warm conditions. This difference was clear in the edited video recordings in two patients.

Table 2 Changes in the diaphragmatic evoked EMG in response to magnetic pulse phrenic stimulation in 26 patients, at two temperatures: cold (31.3 °C) and warm (36.5 °C). L=Latency, D=duration and A=amplitude of the evoked compound action potential as a percentage change from the cold condition. Values are medians (range). The Wilcoxon signed rank test was used for comparisons. Data from the 26 patients were first analysed as one population and also as two separate subgroups (those who received ice slush for myocardial preservation and those who did not)

	Cold	Warm	*P*
All (*n*=26)			
L (ms)	10.1 (8.0–11.8)	8.3 (5.9–10.2)	<0.001
D (ms)	11.8 (2.4–26.3)	9.0 (3.3–24.8)	<0.001
A	100	123 (53–1410)	<0.05
Ice (*n*=16)			
L (ms)	10.3 (8.0–11.8)	7.9 (6.1–10.2)	<0.001
D (ms)	10.6 (2.4–26.3)	8.6 (3.3–22.9)	<0.001
A	100	123 (74–313)	<0.05
No ice (*n*=10)			
L (ms)	9.8 (8.2–11.2)	8.7 (5.9–9.8)	<0.01
D (ms)	12.8 (5.5–23.1)	9.8 (5.7–24.8)	ns
A	100	153 (53–1410)	ns

Table 3 Changes in the diaphragmatic evoked EMG in response to magnetic pulse phrenic stimulation in six patients during a temperature transition from warm (36 °C) to cold (32 °C). Units of measurement and symbols are as in table 2, except that the baseline value for A was in the warm condition

n=6	Warm	Cold	*P*
L (ms)	8.6 (7.5–9.2)	10.9 (9.0–11.8)	<0.05
D (ms)	8.2 (5.8–11.7)	9.4 (5.5–13.8)	ns
A	100	13.9 (10–34)	ns

In the subgroup of six patients also tested during the transition from warm to cold, the mean diaphragmatic "warm" temperature was 34.8 °C (36 °C in the nasopharynx) and "cold" 31.5 °C. On cooling, latency increased significantly by 25% and there were no significant changes in duration (12% increase) or amplitude (80% decrease, see table 3).

A comparison between the subgroup of six patients who received suxamethonium and the subgroup of 20 patients who received vecuronium for intubation of the trachea showed no differences in the EMG variables latency, duration and amplitude between the cold and warm set of measurements.

IMMEDIATE EFFECTS OF ICE SLUSH ON PHRENIC NERVE CONDUCTION

The use of ice slush reduced markedly the amplitude of the left evoked diaphragmatic EMG within 5 min in the four patients monitored throughout the ice slush application, and increased markedly latency and duration, as seen in figure 2. In two of the patients the EMG was abolished during the initial 10 min of ice slush use, no diaphragmatic movement being visible in response to phrenic stimulation. Thus data on latency and duration could not be recorded during this period. Within 15 min, the EMG started to recover and after 55 min the mean values for latency, duration and amplitude were, respectively, 134%, 127% and 76% of pre-ice

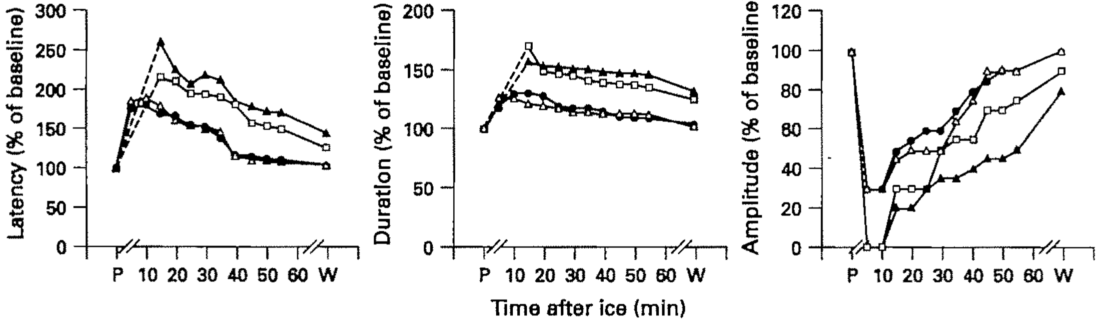

Figure 2 Changes in latency, duration and amplitude, as percentages from baseline pre-ice slush values (P), in the diaphragmatic EMG compound action potential evoked by magnetic pulse stimulation of the left phrenic nerve, in four patients. Values were recorded at 5-min intervals after application of ice slush to the heart and also after systemic warming, just before chest closure (W). In two patients (□ and ▲) the evoked EMG was abolished for 10 min after ice application.

values. By the time the chest was closed, mean values for latency, duration and amplitude were 118%, 115% and 92% of pre-ice values. Only three of the 26 patients failed to recover the latency of the evoked EMG response to within the normal range (less than 9.5 ms) by the end of surgery; two of these patients had received ice slush, but none had difficulty in weaning from mechanical ventilation after surgery. All patients were breathing spontaneously within 6 h of arrival in the recovery ward.

CHANGES IN GASTRIC PRESSURE IN RESPONSE TO PHRENIC STIMULATION

The amplitude of the gastric pressure deflections in response to bilateral phrenic stimulation was more variable from patient to patient than the EMG data. Within each patient, however, variability was comparable with that of the EMG data. The amplitude of the deflection was approximately double during warm compared with cold stimulation in the four patients studied.

Discussion

The main finding in this study was the shortening of latency and increase in amplitude of the evoked diaphragmatic EMG action potential associated with a 5-°C increase in temperature. Even the smaller temperature change (3.3 °C) in the six patients studied during the warm to cold transition caused a significant increase in latency. These findings are not surprising, but provide the first direct evidence of the effects of small changes in temperature on phrenic nerve and diaphragmatic function in humans. This observation is important because the temperatures tested (31, 34.8 and 36 °C) were within the range likely to be found during recovery from major surgery.

Another observation was the marked reduction in amplitude of the EMG of the left hemidiaphragm shortly after a single application of ice slush to the heart. It appeared to temporarily abolish the diaphragmatic twitch response to phrenic stimulation within 10–15 min in approximately 50% of patients (two of four in our series), without subsequent long-term dysfunction.

LIMITATIONS OF THIS STUDY

An important limitation of this study was the emphasis placed on the electromyographic variables to describe the function of the diaphragm. Ideally, we should have measured changes in twitch tension of the diaphragm in response to impulse stimuli, a notoriously difficult technique, only possible in animal experiments. In human studies, measurement of changes in transdiaphragmatic pressure in response to bilateral twitch stimulation of the diaphragm would have been the technique of choice to assess function, provided the chest cavity was not open. As the opportunity of obtaining measurements during relatively rapid changes in temperature occurred only with the chest open, we had no choice in the method of assessing diaphragmatic function other than the EMG and direct observation of diaphragmatic movement. The video recordings of the twitch responses were useful to confirm the impression gained from direct observation but did not provide quantitative data. Intragastric pressure measurements carried out in four patients during bilateral phrenic stimulation aimed at demonstrating a mechanical correlate of the EMG changes. These results, however, must be interpreted with caution because of many factors (for example, the presence of an open chest distorted by the chest retractor) which may have affected the absolute magnitude of the responses. Nevertheless, despite patient-to-patient variation in the amplitude of the baseline pressure deflection, it doubled with the increase in temperature in all four patients tested, which strongly supports the EMG data.

The results obtained, however, simply suggest that there was a degree of muscle weakness associated with 3–5 °C of hypothermia. They do not allow us to predict if this weakness induces a corresponding degree of hypoventilation in a spontaneously ventilating hypothermic patient. A different type of study design, with emphasis on breathing variables, is required to answer this question. It is generally recognized, however, the difficulty in correlating EMG findings with postoperative diaphragm dysfunction.

Ideally, each set of measurements should start with baseline EMG responses at normothermia followed by measurements during hypothermia and then recovery to normothermia. This approach was not possible in the majority of our patients because nasopharyngeal temperature was less than 36 °C after induction of anaesthesia or had decreased to 34–35 °C by the time the chest was open.

The observed effects on the EMG are unlikely to be related to the anaesthetic drugs used. Plasma propofol concentrations were within the range of light anaesthesia and decreased slightly, but not significantly, between measurements. I.v. induction agents have been shown to reduce the amplitude of the leg EMG response to magnetic cortical stimulation[17 18] whereas fentanyl has no effects. Data are not available on the direct effects of anaesthetic agents on the motor neurone, skeletal muscle or the neuromuscular junction, except for volatile agents which depress the EMG response evoked by cortical stimulation[19] and the excitability of spinal motor neurones.[20] Vecuronium, used for intubation of the trachea in 20 patients, could have affected the EMG responses as there is evidence that hypothermia prolongs its effect.[21] It is unlikely that vecuronium could account for the changes in EMG variables observed during the short period of systemic warming (approximately 15 min) occurring at least 3 h after the single bolus administration of a moderate dose for intubation. The identical responses observed in the six patients given suxamethonium for intubation also refutes a possible effect of residual block. We do not have a plausible explanation for the slight but significant increase in mean plasma potassium concentration associated with systemic warming. It was, however, too small to have physiological effects and did not correlate with individual changes in electrophysiological variables.

CHANGES IN DIAPHRAGMATIC EMG WITH HYPOTHERMIA

On the transition from cold to warm in the 10 patients not exposed to ice slush, the only significant change was the shortening of latency in the evoked EMG response. The lack of significance in the changes in duration and amplitude may be explained by the greater variability in the measurements of duration and amplitude, especially amplitude which was sensitive to small changes in electrode position. In the smaller subgroup of six patients in whom measurements were also made during the transition from warm to cold, again, only latency showed a significant change with cooling, despite the smaller sample size and the smaller temperature change (mean 3.3 °C). The variability in the measurements in this subgroup was noticeably reduced, perhaps because the patient's systemic cooling took place over a much shorter period of time than warming, so the interval between the measurements at the two temperatures was shorter.

EFFECTS OF ICE SLUSH

The duration of the conduction block which we observed with ice slush was much shorter than that reported previously in a similar experimental situation in dogs. Exposure of the dog phrenic nerve to ice slush for 30–60 min caused total phrenic block with a similar, rapid onset (approximately 5 min) but lasting between 6 and 28 days[9] instead of 10–15 min as in our study. This discrepancy may be because of the pericardial sac preventing direct contact between the slush and the phrenic nerve. Duration of exposure to ice may also be important. Rosou and colleagues,[13] who studied patients in whom a special cooling jacket was placed around the heart for much longer periods of time, observed a 23% incidence of prolonged phrenic paresis. It may be noteworthy that two of the three subjects in our study who, despite normothermia had a prolonged latency at the time of chest closure (but no subsequent clinically obvious postoperative dysfunction) had been exposed to ice slush. We did not, however, expect to be able to correlate measurements obtained during surgery with measurements of diaphragmatic dysfunction observed after surgery in such a small number of patients. Given the average incidence of severe diaphragmatic dysfunction after cardiac surgery, it would require study of at least 400 consecutive patients to be able to include one with this complication. The fact that all patients in this study had an uneventful recovery and were breathing spontaneously 6 h after surgery does not exclude the presence of diaphragmatic dysfunction, especially during the first 3 h of recovery. A different study design is required to examine the effects of postoperative hypothermia on respiratory variables.

The clinical implications of our study are mostly apparent when attempts are made to reduce the time to extubation after cardiac anaesthesia (often referred to as "fast tracking"). Most patients, if normothermic, are able to maintain acceptable gas exchange when spontaneous ventilation returns shortly after closure of the skin. If hypothermia is present, however, there is diaphragmatic dysfunction and we believe that some type of mechanical assistance to breathing is justified until normothermia is achieved, especially in susceptible patients such as the elderly or the obese.

Changes in regulators of the circulation in patients undergoing lung surgery

J. Boldt, M. Papsdorf, D. Uphus, M. Müller and G. Hempelmann

Summary

Several vasoactive substances are responsible for control of the circulation. During lung surgery these substances may be influenced either by the technique of anaesthesia or by altered production and elimination. We have studied plasma concentrations of important regulators of the circulation in patients undergoing lobectomy using two different regimens: propofol–low-dose fentanyl–nitrous oxide–vecuronium, tracheal extubation immediately after surgery (group Ia (n=15)); fentanyl–midazolam–pancuronium, delayed tracheal extubation in the intensive care unit (ICU) (group Ib (n=15)). We also studied patients undergoing pneumonectomy using fentanyl–midazolam–pancuronium anaesthesia (group II (n=15)). Plasma concentrations of endothelin-1 (ET-1), atrial natriuretic peptide (ANP), vasopressin, catecholamines (adrenaline, noradrenaline) and 6-keto-prostaglandin F_{1alpha} were measured. Extensive haemodynamic monitoring was performed using a pulmonary artery catheter. All measurements were carried out after induction of anaesthesia (baseline values), 30 min after one-lung ventilation (OLV) was induced, at the end of surgery, 2 h after surgery in the ICU and on the first day after operation. CVP, PAP and PCWP increased in all groups during OLV but remained increased only in patients undergoing pneumonectomy. CI decreased significantly in the pneumonectomy group but did not differ between both lobectomy groups. SVRI was lowest in the propofol-treated patients and remained highest in the pneumonectomy group. Plasma concentrations of adrenaline and noradrenaline did not change in group Ia, but increased significantly in groups Ib (noradrenaline: from 267 (67) to 496 (91) pg ml^{-1}) and II (adrenaline: from 237 (59) to 681 (210) pg ml^{-1}). Plasma concentrations of ET-1 remained almost unchanged in groups Ia and Ib, whereas they increased in pneumonectomy patients (from 2.63 (0.3) to 6.61 (1.01) pg ml^{-1}). Vasopressin plasma concentrations increased during OLV in all groups; they were lowest in the propofol patients and highest in patients undergoing pneumonectomy (32.2 (10.2) pg ml^{-1}). Plasma concentrations of ANP and 6-keto-prostaglandin F_{1alpha} increased in all groups during OLV and remained increased only in the pneumonectomy group. (*Br. J. Anaesth.* 1997; **79**: 733–739).

Key words
Surgery, thoracic. Cardiovascular system, responses. Sympathetic nervous system, catecholamines. Sympathetic nervous system. Ventilation, one lung.

During major surgery, circulatory stability is of major importance for patient outcome.[1] Functional disturbances in the microcirculation must also be avoided because it has become increasingly clear that reduction in microcirculatory blood flow is an important trigger for the development of multiple organ dysfunction syndrome.[2] Neural control mechanisms and various circulating vasoactive substances are involved in the control of organ perfusion in this situation. Humoral agents which are known to alter (micro-) circulatory blood flow include adrenaline, noradrenaline and vasopressin. Atrial natriuretic peptide (ANP) has been detected more recently and it participates in the regulation of vasomotor tone either directly by affecting vascular tone or indirectly by influencing hormone homeostasis (e.g. renin release, modifying catecholamine synthesis).[3 4]

In recent years there has been a large body of literature suggesting that the vascular endothelium is involved in the regulation of regional microcirculatory blood flow.[5] Among the substances released from the endothelium to maintain haemostasis and circulatory homeostasis is the 21-amino acid endothelin-1.[6 7] It appears to have a greater vasoconstrictor effect than any other substance, including vasopressin and noradrenaline. Its vasoconstrictive potency is approximately 10 times that of angiotensin II.[6] In addition to the vascular properties of endothelin-1, interactions with other vasoactive substances may be important (e.g. inhibition of release of catecholamines and renin, stimulation of ANP release).[8] The interactions between these (often opposing) vasoactive forces ultimately determine systemic and regional blood flow.[9]

During thoracic surgery this regulatory system

may be altered by many mechanisms. Surgical stress, the lateral position in association with one-lung ventilation (OLV), clamping of the pulmonary artery and the anaesthetic regimen may result in changes in plasma concentrations of vasoactive substances. It is known that the lung serves not only gas exchange but is also involved in the regulation of circulatory homeostasis: some vasoactive substances are produced by the lung (e.g. angiotensin II, prostaglandins) and others are taken up from the circulation and metabolized (e.g. endothelin, catecholamines).[10–12] Thus surgery of the lung may have a profound influence on regulators of the macro- and microperfusion. This study was designed to determine the influence of different anaesthetic management regimens and different types of lung surgery on plasma concentrations of important vasoactive substances.

Patients and methods

After obtaining institutional review and written informed consent, we studied 30 patients undergoing lobectomy (group I) and 15 patients undergoing pneumonectomy (group II), both caused by primary lung cancer. Mediastinal lymph nodes were dissected extensively in all patients. Patients with renal insufficiency (creatinine >1.5 mg dl^{-1}), liver dysfunction (aspartate aminotransferase (AST) >40 iu $litre^{-1}$, alanine aminotransferase (ALT) >40 iu $litre^{-1}$) or preoperative pulmonary hypertension (mean pulmonary artery arterial pressure (PAP) >30 mm Hg) were excluded. No patient had a history of myocardial infarction in the previous 6 months or had documented valvular heart disease.

Patients in group I were separated into one of two groups before operation according to a randomized sequence. In group Ia ($n=15$), propofol was given for induction of anaesthesia followed by a continuous infusion until the end of operation (range 0.05–0.15 mg kg^{-1} min^{-1}). Fentanyl 2.5 μg kg^{-1} was given for induction of anaesthesia followed by administration of additional fentanyl if necessary (maximum dose 0.5 mg). Propofol infusion was supplemented with 66% nitrous oxide in oxygen. Neuromuscular block was produced by vecuronium. In these patients the trachea was extubated immediately after surgery and the patient taken to the intensive care unit (ICU), breathing spontaneously. In group Ib (standard management, $n=15$), induction of anaesthesia was carried out with thiopentone 400–500 mg, fentanyl 0.1 mg and pancuronium 0.1 mg kg^{-1}. For additional anaesthesia, fentanyl, midazolam and pancuronium were given according to the patient's clinical response. An oxygen–air mixture was used. Mechanical ventilation was continued in the ICU in these patients for at least 2 h after surgery. The trachea was extubated when haemodynamic and respiratory variables remained stable for at least 30 min. Group II ($n=15$) included patients undergoing pneumonectomy and fentanyl–midazolam–pancuronium were used for anaesthesia (same technique as in group Ib). Controlled mechanical ventilation was continued in the ICU until patients breathed spontaneously and cardiorespiratory variables remained stable.

A double-lumen endobronchial tube was used to carry out one-lung ventilation (OLV). Controlled mechanical ventilation was adjusted to maintain Pa_{O_2} at 15–20 kPa and Pa_{CO_2} at 5.3–5.7 kPa. When necessary, 100% oxygen was used during the period of one-lung ventilation (OLV) (aim Sp_{O_2} >90%). In groups 1b and II the double-lumen tube was replaced by a standard tube at the end of surgery.

Extensive intercostal nerve block was performed directly by the surgeon before closure of the chest (0.5% bupivacaine 1.5 mg kg^{-1}). In the ICU, additional intercostal nerve block was used when the patient felt pain and/or piritramide was given i.v. After tracheal extubation, all patients received oxygen 3 litre min^{-1} by nasal tube.

Fluid (low molecular weight hydroxyethylstarch solution (LMW-HES) or Ringer's solution, or both, was given to maintain central venous pressure (CVP) at 10–14 mm Hg throughout the study, packed red blood cells (PRBC) were administered when haemoglobin was <9 g dl^{-1}. Respiratory complications were defined as the need for mechanical ventilation for more than 24 h and cardiocirculatory complications were defined as the need for inotropic support (adrenaline, noradrenaline). The therapeutic management of all patients (volume replacement, pharmacological support, ventilation patterns) was performed by physicians who were not involved in the study.

MEASURED VARIABLES AND DATA POINTS

Heart rate (HR), mean arterial pressure (MAP), pulmonary artery pressure (PAP), pulmonary capillary wedge pressure (PCWP), central venous pressure (CVP) and cardiac output (CO, thermodilution technique) were monitored using a pulmonary artery catheter. From arterial blood samples, plasma concentrations of endothelin-1 (ET-1) were measured by radioimmunoassay (RIA) (Biocode, Sclessin, Belgium[13]). Blood samples were collected in tubes containing 5 mg of editic acid (ethylenedinitro tetraacetic acid) and plasma was separated immediately by centrifugation and stored at −35 °C until analysis. As provided by the manufacturer, normal plasma values in healthy volunteers are 2–4 pg ml^{-1}, the sensitivity of the RIA was 0.5 pg ml^{-1}, and cross reactivity with ET-1 was 100%, with ET-2 34%, with ET-3 64%, with big-ET 2% and with other vasoactive peptides (e.g. angiotensin I and II, bradykinin, ANP) <0.1%. Atrial natriuretic peptide (ANP) (by RIA; Instar Corp., Stillwater, MN, USA[14]), vasopressin (by RIA; Instar Corp., Stillwater, MN, USA[15]), 6-keto-prostaglandin F_{1alpha} (the stable but inactive end product of prostaglandin I_2 (prostacyclin)), using a commercially available enzyme immunoassay kit (TiterZyme, PerSeptive Diagnostics, Cambridge, MA, USA) and catecholamines (adrenaline and noradrenaline; by a high-pressure liquid chromatographic (HPLC) technique with electrochemical detection) were also analysed from arterial blood samples. Standard laboratory variables were also monitored.

Measurements were performed after induction of anaesthesia (supine position, after haemodynamic stability was reached=baseline values), 30 min after atelectasis was induced (=one-lung ventilation (OLV), lateral position), at the end of surgery (supine position), 2 h after the end of surgery (in the ICU) and at the morning of the first day after operation (supine position, in the ICU).

STATISTICAL ANALYSIS

All variables are expressed as mean (SD). One- and two-factorial analyses of variance for repeated measurements (ANOVA, including Scheffe`s test) were used for statistical analysis. Additionally, the Mann–Whitney *U* test and chi-square test were used when appropriate. $P<0.05$ was considered significant.

Results

Patients undergoing pneumonectomy were at higher risk (higher ASA classification) than those undergoing lobectomy (table 1). Three patients undergoing pneumonectomy died during the intensive care period. In patients in group Ia the trachea was extubated at 31 (10) min, in group Ib, 345 (111) min and in patients undergoing pneumonectomy at 611 (219) min after surgery (table 1). Cumulative fluid balance was higher in propofol-treated patients than in the other two groups.

HAEMODYNAMIC STATE

MAP increased significantly during and after OLV in groups Ib and II (table 2). CVP, PAP and PCWP remained increased after OLV only in patients undergoing pneumonectomy, while they normalized in groups Ia and Ib (table 2). CI decreased significantly in patients undergoing pneumonectomy but did not differ in the two other groups. SVRI was lowest in the propofol-treated group and remained highest in patients undergoing pneumonectomy. Pa_{O_2}/FI_{O_2} ratio was comparable in both lobectomy groups (table 2). Pneumonectomy patients showed a significantly lower Pa_{O_2}/FI_{O_2} ratio than those in the groups undergoing lobectomy.

REGULATORS OF THE CIRCULATION

Plasma concentrations of noradrenaline (fig. 1) did not change in propofol-treated patients (group Ia) but increased significantly in the two other groups (group Ib, from 267 (67) to 496 (91) pg ml^{-1} at the end of surgery; group II, from 237 (59) to 681 (210) pg m^{-1}). Plasma concentrations of adrenaline (fig. 1) also increased only in patients in groups Ib and II. ET-1 plasma concentrations remained almost unchanged in groups Ia and Ib (fig. 2). It increased significantly in patients in group II (from 2.63 (0.3) to 6.61 (1.01) pg ml^{-1} at the end of the study). In the perioperative period, vasopressin plasma concentrations (fig. 2) increased similarly in all groups. Two hours after surgery vasopressin concentrations were significantly lower in group Ia (increase from 2.23 (0.88) to 14.8 (3.1) pg ml^{-1}) and significantly higher in patients undergoing pneumonectomy (increase from 2.58 (0.79) to 32.2 (10.2) pg ml^{-1}). On the morning of the first day after operation, plasma concentrations of vasopressin were still significantly highest in the pneumonectomy group (16.9 (3.9) pg ml^{-1}). Plasma concentrations of ANP and 6-keto-prostaglandin F_{1alpha} increased significantly in all groups during OLV (fig. 3). ANP concentrations

returned to baseline values in groups Ia and Ib thereafter, but were still significantly higher in the pneumonectomy group at the end of the study (115.5 (13.1) pg ml^{-1}). Plasma concentrations of 6-keto-prostaglandin F_{1alpha} remained significantly increased until the end of the study in patients undergoing pneumonectomy (60.4 (8.8) pg ml^{-1}).

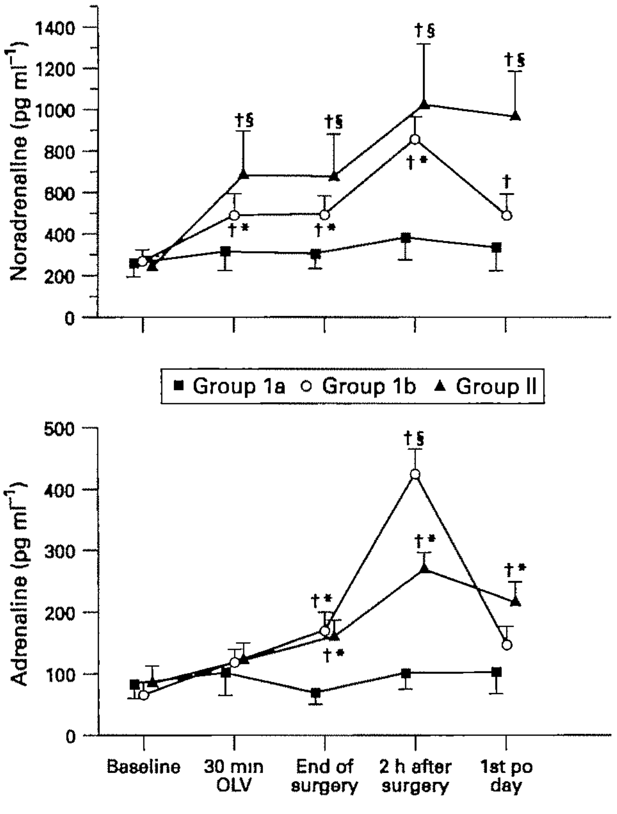

Figure 1 Changes in plasma concentrations of noradrenaline (normal range 180–250 pg ml^{-1}) and adrenaline (normal range 30–85 pg ml^{-1}) in group Ia (propofol patients who underwent tracheal extubation immediately after surgery), group Ib (midazolam–fentanyl patients, extubation in the ICU) and group II (pneumonectomy patients). $P<0.05$ compared with: *group Ia; †baseline values; §groups Ia and Ib.

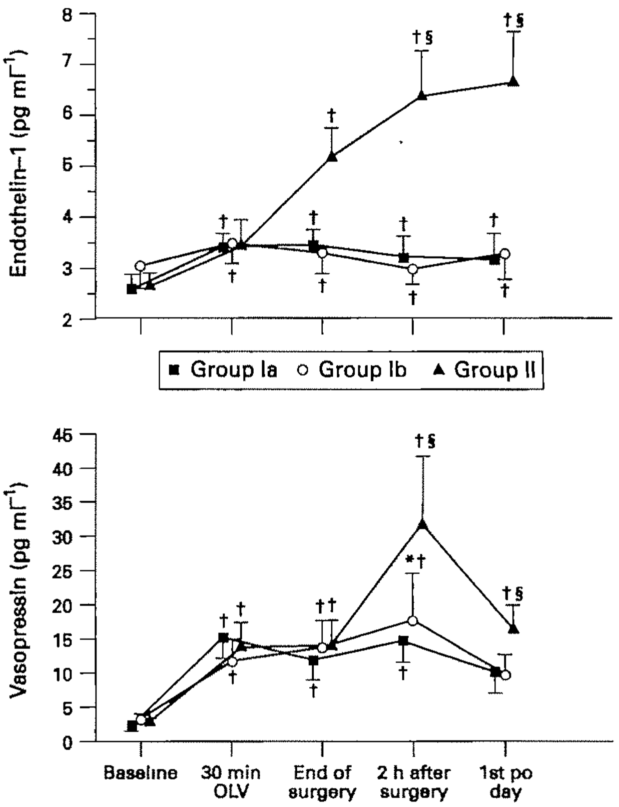

Figure 2 Changes in plasma concentrations of vasopressin (normal range <3.0 pg ml^{-1}) and endothelin-1 (normal range 2.0–5.0 pg ml^{-1}) in the three groups (see fig. 1 for details). $P<0.05$ compared with: *group Ia; †baseline values; §groups Ia and Ib

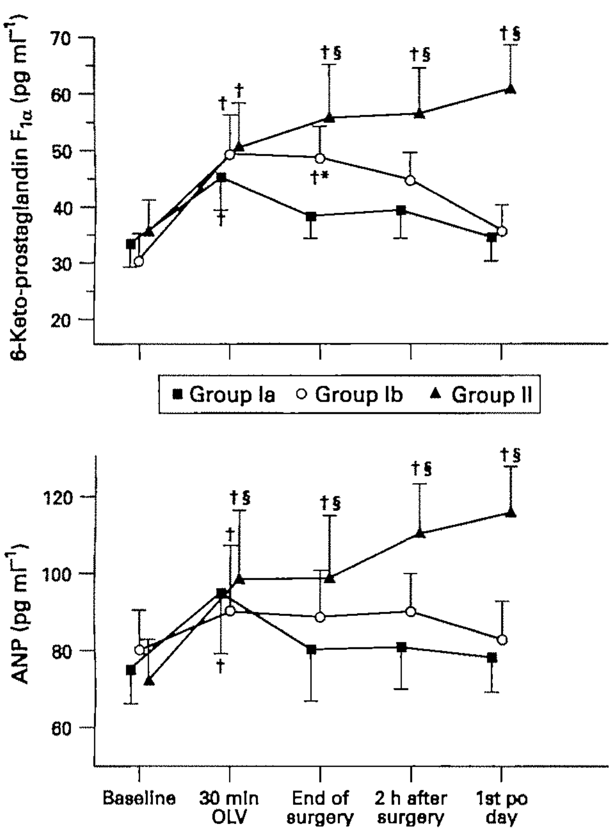

Figure 3 Changes in plasma concentrations of 6-keto-prostaglandin F_{1alpha} (normal values <30 pg ml^{-1}) and atrial natriuretic peptide (ANP) (normal values 20–80 pg ml^{-1}) in the three groups (see fig. 1 for details). $P<0.05$ compared with: *group Ia; †baseline values; §groups Ia and Ib.

Discussion

We found that propofol-treated patients showed early co-operation, were orientated, could sigh and cough on command, and effective physiotherapy was possible earlier in the postoperative period than in the other lobectomy group. Haemodynamic variables in the propofol group were almost comparable with patients in whom an anaesthetic regimen with longer acting anaesthetic substances (midazolam–fentanyl–pancuronium (standard management technique) and subsequent delayed extubation in the ICU were used. CI was slightly higher in propofol-treated patients, possibly because of a lower SVR than in the other group. PAP during OLV was also lower in the propofol than in the other group indicating less increase in right ventricular work. MAP remained stable in propofol-treated patients, probably because of adequate volume replacement which is known to prevent unwanted hypotension during propofol infusion. Plasma concentrations of catecholamines were significantly higher in the anaesthetic regimen with delayed extubation than in propofol-treated patients who underwent extubation immediately after surgery. All other vasoactive substances (ET-1, vasopressin, ANP, 6-keto-prostaglandin F_{1alpha}) were similar between the two groups during the study.

PNEUMONECTOMY PATIENTS

Patients undergoing pneumonectomy showed significant differences both in haemodynamic state and vasoactive regulators of the circulation compared with patients in group Ib in whom the same anaesthetic technique was used. PAP increased during OLV and remained higher than baseline until the end of the study. In a study by Lewis and co-workers,[16] including 20 patients with moderately severe chronic obstructive pulmonary disease undergoing pneumonectomy, only 10% had a normal PAP in the immediate postoperative period. Others also reported a marked increase in right ventricular afterload during OLV and after completion of resection.[16–18] Increased right ventricular (RV) afterload in this situation most likely results from increased pulmonary vascular constriction secondary to hypoxic vasoconstriction (HPV), pulmonary microvascular plugging and decreased pulmonary vascular compliance.[17]

Plasma concentrations of potent vasoconstrictive substances (e.g. vasopressin, ET-1, noradrenaline) increased significantly in patients undergoing pneumonectomy. All are potent vasopressors which may act particularly in the intestinal circulation with detrimental consequences for the organism.[19] Activation of the sympathetic system is caused by a complex interaction of different stimuli, for example hypotension, hypovolaemia and hypoperfusion. The increase in plasma concentrations of catecholamines reflects the magnitude of the (reflectory) sympathetic nervous system response in this situation. In recent years it has become obvious that in addition to "systemic" regulators of the circulation (e.g. catecholamines), substances released by the endothelium are also involved in the pathophysiology of circulatory abnormalities.[20 21] ET-1 is one of these substances which can induce regional vasoconstriction followed by impaired organ blood flow. ET-1 is released by pathophysiological states that are characterized by limitation of cardiac output or by hypotension. Apart from the direct vasoconstrictive actions of ET-1, it may also influence the circulation by altering other regulator systems. Thus ET-1 was reported to stimulate the release of catecholamines and renin[22] thus possibly contributing to vasoconstriction and reduced blood flow at the microcirculatory level. In contrast, ET-1 also influences ANP secretion increasing circulating ANP in dogs[23 24]: ANP may function as a negative feedback regulator of ET-1 and the vasoconstrictive actions of ET-1 are opposed by the release of other vasoactive substances, including ANP.

Plasma concentrations of ANP were significantly increased in the pneumonectomy group. A linear relationship between ANP plasma concentrations and right atrial (RAP) and pulmonary capillary wedge pressure (PCWP) has been shown.[25] However, this may not be the only mechanism by which plasma concentrations of ANP were increased. Endothelin has been shown to stimulate release of ANP *in vivo* and *in vitro*.[26] Both substances have important interactions on the vascular level: ANP appears to counteract the contractile response to endothelin.[27] Additionally, results from animal and human studies suggest that adrenaline (which was also increased in pneumonectomy patients) stimulates ANP secretion.[24] 6-Keto-prostaglandin F_{1alpha} was also increased in the pneumonectomy patients. Nakae and colleagues[28] showed that it may serve as a marker of illness severity. Pneumonectomy patients showed delayed stabilization of haemodynamic state and pulmonary function resulting in delayed tracheal extubation in the ICU. Thus it can be assumed that these were at higher risk of developing cardiopulmonary complications.

The significant changes in plasma concentrations of potent vasoactive substances may have important consequences for organ function. Altered microregional vascular tone results in some capillary regions being over perfused while others are under perfused.[29] Although three of the 15 pneumonectomy patients and none of the lobectomy patients died during their stay in the intensive care unit, the population was too small to draw definite conclusions on whether or not the measured vasoactive substances were responsible for the difference in survival rates between the groups.

The reasons for the more pronounced changes in important regulators of the circulation in the pneumonectomy patients can only be speculative. It is unlikely that the technique of anaesthesia was the major reason because lobectomy patients in group Ib underwent the same anaesthetic management (midazolam–fentanyl–pancuronium) but showed only moderate changes in plasma concentrations of the vasoactive substances. As indicated by the higher ASA classification, severity of illness in the pneumonectomy patients appeared to be higher than in the two lobectomy groups resulting in less cardiopulmonary reserve. Last but not least, altered production or uptake may be the reason for the increased plasma concentrations of some of the vasoactive substances. There is convincing evidence that the lung is a highly metabolic organ which contributes markedly to production and elimination of various substances (e.g. noradrenaline, prostaglandins, ANP). Endothelial cells appear to play a particular role in this process. The pulmonary endothelium has an immense surface area and actively participates in production and inactivation of vasoactive substances.[30] As an example, the lung is apparently the most relevant organ in rapid clearance of endothelin.[31] The pulmonary circulation also has the potential to generate endothelin from its own endothelium given an appropriate stimulus such as hypoxia.[23] This may be one explanation for the higher plasma concentrations of ET-1 in our pneumonectomy patients. The lung may also participate in regulation of the action of ANP secreted by the right atrium by active metabolism.[4] Interactions of ET-1 with other vasoactive substances may have further influenced their plasma concentrations (e.g. inhibition of release of catecholamines and renin by ET-1, stimulation of ANP release by ET-1).[8]

In summary, regulation of the macro- and microcirculation is dependent on both centrally originated and locally derived control mechanisms. The anaesthetic regimen in patients undergoing major thoracic surgery was only of limited value in affecting important regulators of the circulation. Thus an anaesthetic regimen using more short acting substances with early tracheal extubation of the patient appeared to be without detrimental effects on the (micro-) circulation. More extensive lung surgery (e.g. pneumonectomy) was followed by more extensive changes in plasma concentrations of important regulators of organ perfusion. As the (micro-) circulatory flow abnormalities appear to be a major determinant of development of organ function further studies are needed to assess whether its manipulation may improve patient outcome.

I. v. fentanyl decreases the clearance of midazolam

I. HASE, Y. ODA, K. TANAKA, K. MIZUTANI, T. NAKAMOTO AND A. ASADA

Summary

We have examined the effect of fentanyl on the pharmacokinetics of midazolam in patients undergoing orthopaedic surgery. Thirty patients were allocated randomly to receive fentanyl 200 μg and midazolam 0.2 mg kg^{-1} (fentanyl group, n=15) or placebo and midazolam 0.2 mg kg^{-1} (placebo group, n=15) in a double-blind manner for induction of anaesthesia. Anaesthesia was maintained with nitrous oxide and isoflurane. Systemic clearance of midazolam was decreased by 30% (P=0.002) and elimination half-time was prolonged by 50% (P=0.04) in the fentanyl group compared with the placebo group. There were no differences in the distribution half-time or volume of distribution at steady state between the two groups. These findings indicate that elimination of midazolam was inhibited by fentanyl during general anaesthesia. (*Br. J. Anaesth.* 1997; **79**: 740–743).

Key words

Hypnotics benzodiazepine, midazolam. Analgesics opioid, fentanyl. Enzymes, cytochrome P450. Pharmacokinetics, midazolam. Pharmacokinetics, fentanyl.

Midazolam is a widely used anaesthetic with a short duration of action.[1 2] It is metabolized by the hepatic microsomal cytochrome P4503A (CYP3A),[3 4] which is inhibited by various drugs, including antibiotics, antimycotics and calcium channel blocking agents, resulting in prolonged drowsiness and inhibition of psychomotor performance.[5–7] Midazolam is used frequently in combination with opioids for anaesthesia and sedation. CYP3A plays a role in the metabolism of fentanyl[8] and it may occur that one drug inhibits the metabolism of another drug when they are metabolized by the same P450 isozymes.[9] Therefore, the metabolism of midazolam may also be inhibited by simultaneously administered fentanyl, with prolongation of the duration of action of midazolam. Although the pharmacokinetics of midazolam have been studied extensively,[1 2 5–7] the effect of fentanyl on the pharmacokinetics of midazolam has not been elucidated. As midazolam frequently induces hypoxaemia and apnoea when used with fentanyl,[10] it is important to examine the effect of fentanyl on the pharmacokinetics of midazolam. Our objective was to investigate the effect of i.v. fentanyl on the pharmacokinetics of i.v. midazolam.

Patients and methods

The reference substance of midazolam was a gift from Hoffmann-La Roche Ltd (Nutley, USA). Diazepam and fentanyl were purchased from Takeda Pharmaceuticals Co. Ltd (Tokyo, Japan) and from Sankyo Pharmaceuticals Co. Ltd (Tokyo, Japan), respectively. Other reagents and organic solvents were obtained from Wako Pure Chemical Industries (Tokyo, Japan). A C18-column (TSKgel ODS-120T) was obtained from the Tosoh Corp. (Tokyo, Japan).

STUDY DESIGN

We used a double-blind, randomized, placebo-controlled study design with parallel groups. Based on our preliminary study, we determined that 15 patients would be needed in each group to demonstrate a 50% increase in the elimination half-time of midazolam at a level of significance of P=0.05 and power of 80%. Prolongation of the elimination half-time of midazolam inhibits psychomotor performance of patients and delays tracheal extubation after operation.[5 6]

After obtaining approval from the Institutional Ethics Committee and written informed consent, we studied 30 patients, ASA I, aged 17–40 yr, undergoing orthopaedic surgery. Patients were allocated randomly to receive fentanyl or placebo. All staff in the operating room and in the recovery room were unaware of the randomization code. Exclusion criteria were hepatic dysfunction, heart disease, treatment with any known inhibitor or inducer of CYP3A enzymes, and morbid obesity. Patients undergoing laparotomy were also excluded.

All patients were premedicated with secobarbitone 100 mg and atropine 0.5 mg i.m., given 60 min and 30 min before induction of anaesthesia, respectively. Anaesthesia was induced with fentanyl 200 μg i.v.,

followed by midazolam 0.2 mg kg^{-1} i.v. 1 min later (fentanyl group). Fentanyl was diluted with saline to a total volume of 10 ml and injected over 1 min. In the placebo group, the same volume of saline was administered instead of fentanyl, followed by midazolam 0.2 mg kg^{-1}. Isoflurane and 66% nitrous oxide in oxygen were used to maintain anaesthesia. Tracheal intubation was facilitated with vecuronium 0.1 mg kg^{-1} i.v. After tracheal intubation, the lungs were ventilated to maintain end-tidal carbon dioxide concentration at 4.6–5.3 kPa. End-tidal carbon dioxide tensions and concentrations of isoflurane were measured with a gas analyser (Capnomac Ultima, Datex Instrumentarium Corp., Helsinki, Finland). The minimum alveolar anaesthetic concentration hours (MAC-h) exposure was calculated from the percent anaesthetic concentration and duration of exposure. MAC values of 1.15% were used for isoflurane.[11] The trachea was extubated after operation and patients were transferred to the recovery room.

BLOOD SAMPLING AND MEASUREMENT OF PLASMA CONCENTRATIONS OF MIDAZOLAM

To measure plasma concentrations of midazolam, blood samples were obtained from an indwelling arterial cannula before and 5, 10, 15, 20, 30, 45, 60, 90 and 120 min after administration of midazolam, and every 60 min thereafter until 360 min. Additional blood samples were obtained to measure plasma concentrations of fentanyl at 5, 15, 60 and 180 min after administration of midazolam. Plasma was separated within 30 min and stored at −40°C until analysis. The amount of blood collected for the study was less than 100 ml, and insignificant relative to surgical loss.

Plasma concentrations of midazolam were measured by high-pressure liquid chromatography (HPLC) using a method described previously with modifications.[12] Briefly, HPLC was carried out with a mobile phase consisting of 50% acetonitrile and 0.1% acetate (v/v) in distilled water at a flow rate of 1.5 ml min^{-1} at 45°C, with midazolam and an internal standard, diazepam, detected at a wavelength of 250 nm. The limit of quantitation was 1 ng ml^{-1}. The coefficients of day-to-day variation were 8.6% at 30 ng ml^{-1} (n=18) and 5.1% at 500 ng ml^{-1} (n=17). Fentanyl was quantified by a radioimmunoassay technique as reported previously.[13 14]

PHARMACOKINETIC CALCULATIONS AND STATISTICS

The pharmacokinetics of midazolam were analysed with a two-compartment open model using SAAMII for the Macintosh computer (SAAM Institute, Seattle, WA, USA) as reported previously.[2] The pharmacokinetics of midazolam were characterized by systemic clearance (*Cl*), distribution and elimination half-times ($T_{1/2}{}^{\alpha}$ and $T_{1/2}{}^{\beta}$, respectively) and steady-state volume of distribution (V^{ss}). Systemic clearance was defined as dose/areas under the plasma concentration–time curves (AUC). AUC was calculated by the trapezoidal rule, and other pharmacokinetic variables were calculated using standard formulae.[1] All data are expressed as mean (SD). Patient characteristics and pharmacokinetic variables of the groups were compared using the Student's t test. Data were analysed with the Statview J version 4.5 (Abacus Concepts, Inc., Berkeley, USA) and differences were considered significant if $P<0.05$.

Results

There were no significant differences between the two groups in patient age, weight, height or duration of anaesthesia (table 1). There were no significant differences in isoflurane MAC-h between the two groups. Arterial pressure and heart rates were almost unchanged and there were no differences between the groups at any blood sampling time during the study. All patients awoke immediately after

Table 1 Patient data and details of anaesthesia for the placebo and fentanyl groups (mean (SD or range) or number). Values were compared between groups using the Student's t test. No significant differences between groups

	Placebo group (n=15)	Fentanyl group (n=15)
Sex (M/F)	10/5	9/6
Age (yr)	28 (17–40)	28 (18–40)
Weight (kg)	58 (11)	60 (10)
Height (cm)	167 (6.9)	166 (9.4)
Duration of anaesthesia (min)	268 (92)	219 (123)
Dose of isoflurane (MAC-h)	3.58 (1.25)	3.38 (2.11)

Table 2 Pharmacokinetic variables for midazolam area under the plasma concentration–time curve (AUC), systemic clearance (*Cl*), steady-state volume of distribution (V^{ss}), distribution half-time ($T_{1/2}{}^{\alpha}$) and elimination half-time ($T_{1/2}{}^{\beta}$). Values were compared between groups using the Student's t test

	Placebo group	Fentanyl group	P
AUC(0–∞) (ng ml^{-1} h)	418.5 (96.9)	645.7 (226.8)	0.001
Cl (ml min^{-1} kg^{-1})	8.4 (2.1)	5.9 (1.9)	0.002
V^{ss} (litre kg^{-1})	1.2 (0.5)	1.3 (0.5)	ns
$T_{1/2}{}^{\alpha}$ (min)	17.0 (9.5)	23.3 (8.2)	ns
$T_{1/2}{}^{\beta}$ (min)	146 (62)	217 (114)	0.04

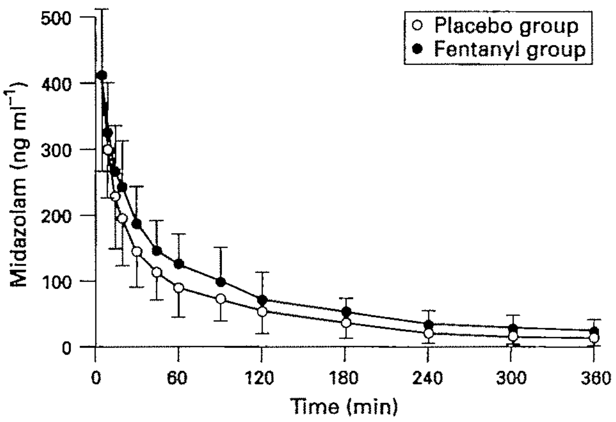

Figure 1 Plasma concentrations of midazolam after i.v. administration of midazolam (mean, SD). Anaesthesia was induced with fentanyl 200 µg and midazolam 0.2 mg kg^{-1} (fentanyl group) or with saline and midazolam 0.2 mg kg^{-1} (placebo group).

discontinuation of inhalation anaesthesia, and the trachea was extubated. No patient developed hypoxia or hypercapnia after operation. Duration of anaesthesia was less than 360 min for 13 patients in the placebo group and for 13 patients in the fentanyl group, and blood sampling was performed in the recovery room after the end of operation.

Systemic clearance, V^{ss}, $T_{1/2}{}^{\alpha}$ and $T_{1/2}{}^{\beta}$ for midazolam in the placebo group were similar to those reported previously.[5 6] There were no differences in V^{ss} or $T_{1/2}{}^{\alpha}$ between the placebo and fentanyl groups (table 2). In the fentanyl group, systemic clearance of midazolam was decreased by 30% ($P=0.002$) and $T_{1/2}{}^{\beta}$ was prolonged by 49% ($P=0.04$) compared with the placebo group, suggesting that elimination of midazolam was prolonged by a single dose of fentanyl administered 1 min before midazolam (fig. 1, table 2). Plasma concentrations of fentanyl were 3.57 (1.29), 1.70 (0.54), 0.78 (0.23) and 0.48 (0.12) ng ml^{-1} at 5, 15, 60 and 180 min after administration of midazolam ($n=6$), and comparable with those reported previously.[15]

Discussion

There are many reports describing the pharmacokinetics of midazolam with or without opioid analgesics,[1 2 5–7] and combined use of midazolam with such analgesics has been shown to have a supra-additive hypnotic effect and to induce respiratory depression.[10 16] However, there have been no studies of the effect of fentanyl on the pharmacokinetics of midazolam. In this study, we found that fentanyl reduced significantly the clearance of midazolam in a anaesthetic procedure commonly used in clinical practice. Plasma concentrations of midazolam were less than the amnesic level at the end of operation, and no patient exhibited delayed emergence from anaesthesia. However, the prolonged effects of midazolam were reported to be a result of inhibition of clearance of midazolam,[6 7] suggesting that persistent amnesia and respiratory depression may occur when midazolam is used with fentanyl.

The pharmacokinetics of midazolam are influenced by agents which are metabolized by CYP3A or influence CYP3A activities, including antibiotics, antimycotics and calcium channel blocking agents.[5–7] As fentanyl is also metabolized selectively by CYP3A,[8] the decrease in systemic clearance of midazolam observed in our study was probably induced by competitive inhibition of CYP3A by fentanyl. Isoflurane is also metabolized by cytochrome P450, whereas CYP2E1 is involved exclusively in the metabolism of isoflurane, and isoflurane has no effect on CYP3A activity.[17 18] We used secobarbitone for premedication in both groups. Although some barbiturates induce CYP3A isoforms, it takes several days to increase the level of CYP3A in the liver and to influence drug metabolism in vivo.[19 20] In this study, plasma concentration of midazolam was measured within 7 h after administration of secobarbitone, suggesting that secobarbitone had no effect on the CYP3A level and pharmacokinetics of midazolam.

Metabolism of midazolam may also be influenced by hepatic blood flow, as the hepatic extraction ratio of midazolam is intermediate.[1] Hepatic blood flow is decreased by hypocapnia, positive pressure ventilation and laparotomy.[21 22] In our study, normocapnia was maintained and no patient underwent laparotomy. Although isoflurane may also affect hepatic blood flow,[23] the mean concentration of isoflurane was comparable in the two groups. Moreover, the pharmacokinetic variables in the placebo group were comparable with those reported for healthy volunteers,[5 6] suggesting that isoflurane and positive pressure ventilation had negligible effects on the pharmacokinetics of midazolam in our study. To our knowledge, there are no reports on the effect of fentanyl on hepatic blood flow in humans *in vivo*. In a study using animals, fentanyl had no effect on hepatic blood flow.[24]

Plasma concentrations of fentanyl in the fentanyl group were comparable with those after i.v. administration to volunteers without concomitant drugs.[15] As wide inter-individual variations are reported for fentanyl pharmacokinetics and pharmacokinetic variables were not obtained as a result of the small number of sampling points in this study,[15] the reason for this finding remains unclear.

Recently, a contribution of CYP3A in the intestine to the metabolism of midazolam has been reported.[25] Because midazolam undergoes first-pass elimination in the intestine, intestinal CYP3A activities should be considered when the pharmacokinetics of orally administered midazolam are analysed.

In summary, we found that the clearance of midazolam was decreased by a single dose of fentanyl, probably as a result of competitive inhibition of CYP3A activity.

Pharmacodynamics of thiopentone: nocifensive reflex threshold changes correlate with hippocampal electroencephalography

D. P. ARCHER AND S. H. ROTH

Summary

The electroencephalographic (EEG) effects of thiopentone have been used extensively in the pharmacodynamic and pharmacokinetic modelling of drug effects in the central nervous system (CNS). Thiopentone has a biphasic (enhancement followed by inhibition) effect on nocifensive reflexes that occurs in a dose range similar to that which activates the EEG. In this study we have used rats chronically instrumented with hippocampal EEG (hEEG) electrodes to simultaneously characterize the effects of thiopentone on the hEEG and nocifensive reflex thresholds. Enhancement of these two measures of CNS effect correlated well with plasma thiopentone concentrations of 10–30 μg ml^{-1} (35–75 μmol $litre^{-1}$) but maximal reflex enhancement occurred at concentrations of 3 μg ml^{-1} (11 μmol $litre^{-1}$) less than the peak hEEG effect. The results validate the usefulness of nocifensive reflex thresholds for measurement of the CNS effects of thiopentone at subanaesthetic concentrations. (*Br. J. Anaesth.* 1997; **79**: 744–749).

Key words
Anaesthetics i.v., thiopentone. Monitoring, electroencephalography. Anaesthesia, depth. Pharmacodynamics, thiopentone. Rat.

The abolition of the withdrawal response to noxious stimulation (nocifensive response) has been used clinically and experimentally to define the state of surgical anaesthesia.[1] Recent studies (for review see Collins, Kendig and Mason[2]) showed that the anaesthetic effects responsible for suppressing nocifensive responses occurred primarily in the spinal cord. Results from our laboratory[3–5] suggest that nocifensive reflex thresholds provide a measure of anaesthetic depth throughout the entire range of clinically relevant thiopentone concentrations. The effects of thiopentone on nocifensive reflex thresholds are concentration dependent, time independent and constant under pseudo-steady state conditions.[4]

The electroencephalogram (EEG) has been used extensively for pharmacodynamic modelling of the CNS effects of thiopentone.[6] Stanski and colleagues have characterized the pharmacokinetics and pharmacodynamics of the CNS site(s) for the EEG effects of thiopentone.[6 7] As thiopentone distributes rapidly within the brain and the spinal cord,[8] the pharmacokinetic profiles of the drug, as measured by the EEG and nocifensive reflex thresholds, should be directly correlated. The objective of this study was to demonstrate that the pharmacodynamic profiles also correlated well. We measured the hippocampal electroencephalogram (hEEG) which, in the rat, has a pharmacodynamic profile similar to that of the cortical EEG[9 10] and the threshold tail withdrawal from pressure.[3–5] The pharmacodynamic relationships between thiopentone concentrations and both the hEEG and nocifensive reflexes are complex, demonstrating a characteristic biphasic relationship (enhancement followed by depression) between plasma drug concentration and CNS effect.[4 6] In this study we have compared the pharmacodynamics of the hEEG and nociceptive effects of thiopentone.

Materials and methods

The experiments were approved by the Animal Care Committee of the University of Calgary and conformed to the guidelines of the Canadian Council on Animal Care and the International Association for the Study of Pain. Male Sprague–Dawley rats weighing 250–350 g were housed in the vivarium (lights on 06:00–18:00) with food and water *ad libitum* for at least 1 week before testing. All studies were conducted between 10:00 and 15:00.

Two experimental designs were used. The aim of the first (five rats) was to characterize the pharmacodynamic relationships between thiopentone, nocifensive reflex thresholds and the hEEG for the full range of clinically relevant plasma concentrations of thiopentone (0–65 μg ml^{-1}; 0–250 μmol $litre^{-1}$). In the second study (five rats), we examined the correlation between hEEG total power and nocifensive reflex thresholds for hyperalgesic thiopentone concentrations of 0–30 μg ml^{-1} (0–115 μmol $litre^{-1}$).

SURGICAL PROCEDURES

Hippocampal electrode insertion

EEG electrodes were inserted into the dentate gyrus of the hippocampal formation as described previously.[11] Briefly, under general anaesthesia (pentobarbitone 50 mg kg^{-1} i.p.), insulated tungsten wires (130 μm in diameter) were inserted bilaterally into the dentate region under stereotactic guidance using the following co-ordinates: 3.4 mm posterior to the bregma, 1.8 mm lateral to the midline and 2.7 mm ventral to the dural surface. The indifferent electrode was an uncoated tungsten wire placed in the cortex. During electrode insertion, spontaneous output from the dentate electrode was monitored on an oscilloscope with an audio monitor. The position of the electrodes was optimized by selecting the region of maximum spontaneous output. Electrodes were fixed with dental acrylic to stainless steel screws threaded into the skull and attached to a connector base mounted to the skull with acrylic. Rats were allowed 1 week to recover from surgery. At that time, inspection of the hEEG confirmed the presence of typical hippocampal theta rhythm in 10 rats that were then studied using the measurement techniques outlined below. Two animals did not demonstrate adequate hEEG 1 week after electrode placement and were excluded from the study. In all animals, movement, feeding and grooming were normal after electrode placement. Histological examination for electrode placement previously demonstrated minimal damage to the hippocampus.[11]

Vascular cannulation

Vascular catheters were inserted into rats that had successful electrode placement. Under general anaesthesia with halothane (2–3% in oxygen), 10 mm of polyethylene tubing (internal diameter 0.58 mm) were inserted into the left femoral artery and vein under direct vision, the wound edges infiltrated with 1% lignocaine and the wound closed. Each animal was partially restrained in a plaster cast, which extended from the ankles to the upper abdomen, and then taped to a wooden block. This technique is used commonly in radioautographic measurements of cerebral blood flow and metabolism, and has been shown not to affect withdrawal reflex thresholds to tail pressure in the rat.[3 12] Animals were allowed 2 h[13] to eliminate halothane. The physiological effects of infusion of thiopentone were assessed with measurements of mean arterial pressure, arterial blood-gas tensions and packed cell volume.

ELECTROENCEPHALOGRAPHIC PROCEDURES

Recordings of hEEG activity were made (180 min) using a Grass model 7D Polygraph with Wide Band AC EEG pre-amplifier model 7P5B (Grass Medical Instruments Co., Quincy, MA, USA). Filter settings were: 1 Hz for the half amplitude low filter and 35 Hz for the half amplitude high filter. Signals were stored on video cassette using a Neuro-corder Interface (Neuro Data Instruments Co., NY, USA, model DR-484) for subsequent spectral analysis. Each hEEG recording was marked audibly for the start of each measure of nociception in the experiment. At each of the planned measurement times in the study, withdrawal latency was measured during a period when the animal was resting quietly. A 27.5-s segment of data recorded just before measurement of withdrawal latency was subjected to power spectral analysis using software developed in this laboratory. Each segment was divided into 2.5-s epochs and the analysed results of 11 epochs were averaged to generate mean values for total power ($voltage^2$/Hz) and power density (proportion of total power) in three frequency bandwidths: 0–4 Hz, 4–12 Hz and 12–25 Hz.

MECHANICAL WITHDRAWAL THRESHOLD

We used analgesimetry to assess the threshold for the nocifensive reflex responses to noxious pressure stimulation in the tail. The threshold for withdrawal of the tail in response to pressure (mechanical withdrawal threshold, MWT) was measured with an Analgesy-Meter (Stoelting Instruments, Chicago, IL, USA), as described previously.[3–5] The end-point of each measurement, the first movement of the tail sufficient to displace the tail from the plinth, was identified by an observer blinded to the instrument scale. A second observer recorded the applied pressure. MWT was calculated as the average of three measurements.

DRUG ADMINISTRATION AND MEASUREMENT

In the first study, each animal was subjected to two timed sequences of MWT testing. During the first (control) sequence, animals received an infusion of saline 0.15 ml min^{-1}; MWT was measured at 0, 2, 4, 6, 8, 12, 16, 20, 25 and 30 min after the start of the infusion. Animals were then allowed a rest period (no stimulation for 60 min) before the second (thiopentone infusion) sequence. An infusion of thiopentone at a rate of 0.67 mg kg^{-1} min^{-1} (2.5 μmol kg^{-1} min^{-1}) in normal saline 0.15 ml min^{-1} was selected on the basis of previous studies.[3–5] The goal was to produce a gradual increase in plasma thiopentone concentration, achieving plasma concentrations of 20–30 μg ml^{-1} (75–115 μmol $litre^{-1}$) by the end of the 30-min infusion and to produce nearly complete suppression of the EEG by 60 min. A plateau in plasma thiopentone concentrations was anticipated to occur after 30 min of infusion, and the infusion rate was doubled at that time. During infusion of thiopentone, MWT was measured in the same time sequence as for the control measurements and then every 10 min, for a total of 70 min.

For the second study, we limited the duration of drug infusion (0.67 mg kg^{-1} min^{-1}; 2.5 μmol kg^{-1} min^{-1}) to 20 min. Measurements of plasma thiopentone concentrations and CNS effect (reflex threshold and hEEG) were made before and at 2, 4, 6, 8, 12, 16 and 20 min after the start of infusion of thiopentone. Arterial blood-gas tensions were measured before and after 20 min of infusion.

Plasma concentrations of thiopentone were measured by HPLC as described previously.[3] The limit of detection was 0.3 μg ml^{-1}, accuracy ±4.5% and coefficient of variation +5%. Shed blood (200 μl per sample) was replaced with three times the volume of normal saline.

DATA ANALYSIS

To facilitate comparison of hEEG and withdrawal response effects of thiopentone on the hEEG, MWT was expressed as a percentage of pretreatment or control values in each rat. We then transformed the withdrawal response data by the function: withdrawal response=1/ MWT×100. This derived variable was then comparable with activation of the hEEG shown by the maximal total power of the EEG which was also expressed as a percentage of pretreatment total power. These data were then analysed for each rat individually for three of the descriptors of a biphasic relationship[6 7]: maximal CNS effect, plasma concentration at maximal effect ($C_p$max) and the plasma concentration at 50% inhibition of the response. The area under the plasma thiopentone–effect curve (AUC), calculated by the linear trapezoidal method, was used to determine the centroid concentration, $C_p$centroid (thiopentone concentration for which the concentration–effect curve is divided equally along the concentration axis). The mean values of the descriptors for hEEG power and withdrawal response were compared by paired Student's *t* test. Statistical significance was taken as $P<0.05$. Results are given as mean (95% confidence interval).

The hEEG pharmacodynamic data obtained in study 1 were analysed by progressive polynomial regression from zero to third order. The "best fit" was selected as the lowest order polynomial that produced a marked increase in the incremental *F* value (*F*=incremental variation from the dependent variable mean/residual variation about the regression curve).

SigmaStat and SigmaPlot software (Jandel Scientific, San Rafael, CA, USA) were used to perform the statistical analyses, graphics and curve fitting.

Results

PHYSIOLOGICAL EFFECTS OF THIOPENTONE

The physiological effects of infusion of thiopentone in study 1 are summarized in table 1. After 30 min of thiopentone infusion, there were no significant deviations in any of these variables from values observed before infusion. As expected, after 60 min of drug infusion, animals were hypotensive, hypothermic and hypoxaemic, with significant respiratory acidosis. Blood letting had also resulted in a decrease in packed cell volume after 60 min. The focus of the study was during the initial 20–30 min of infusion. There were no changes in the physiological variables in any of the animals at any time during the second study (thiopentone infusion limited to 20 min).

STUDY 1: EFFECTS OF THIOPENTONE ON NOCIFENSIVE REFLEX THRESHOLDS

Mean values of MWT were similar when measured before the control infusion (235, 116–354 g), after the control infusion (237, 165–309 g) and before the thiopentone infusion (268, 164–372 g) (repeated measures ANOVA, $P=0.310$). As shown in figure 1, the threshold for withdrawal to tail pressure did not change during the control period, decreased after the start of thiopentone infusion and then increased when plasma concentrations of thiopentone reached 30–40 μg ml^{-1} (110–150 μmol $litre^{-1}$). Plasma concentrations of thiopentone associated with the peak of reflex responsiveness (C_p1/MWT max) were 13 (10–16) μg ml^{-1} (68, 38–98 μmol $litre^{-1}$) (table 2).

STUDY 1: INFLUENCE OF THIOPENTONE ON hEEG

The hEEG did not change during infusion of saline. The biphasic effect of infusion of thiopentone on the hEEG is shown in figure 2 (one-way Friedman repeated measures ANOVA on ranks, P<0.001). Total power increased progressively until plasma thiopentone concentrations of 20–30 µg ml^{-1} (75–115 µmol litre^{-1}) were reached. The maximum value of total power was 195 (164–226) % of control, achieved at a mean plasma thiopentone concentration of 16 (10–26) µg ml^{-1} (68, 38–98 µmol litre^{-1}; P=0.008). Total power then decreased progressively to a minimum of 22 (11–33) % (P=0.008 *vs* control) at a thiopentone concentration of 61 (49–72) µg ml^{-1} (231, 185–272 µmol litre^{-1}). Power density (proportion of total power in the three bandwidths examined) did not change during infusion of thiopentone (P=0.42), suggesting that the primary effect of thiopentone infusion was on hEEG amplitude.

The pharmacodynamics of thiopentone with respect to the hEEG and withdrawal response thresholds were characterized by four descriptors (table 2). These descriptors were maximal effect (compared with control) and plasma thiopentone concentrations at maximal effect ($C_P$max), at the centroid ($C_P$centroid) and at the point of 50% inhibition. Comparison of the pharmacodynamic descriptors (table 2) shows that $C_P$max and $C_P$centroid were less for the nocifensive reflex measure of CNS effect than for hEEG total power. This suggests that although both CNS effects show enhancement at plasma thiopentone concentrations in the range 10–20 µg ml^{-1} (38–76 µmol litre^{-1}), the effects on nociception occurred at slightly lower plasma thiopentone concentrations than for hEEG total power. As the effect site kinetics appear to be similar for EEG and nociception,[14] the nocifensive response would appear to be more sensitive to thiopentone than the hEEG response.

STUDY 2: CORRELATION BETWEEN hEEG TOTAL POWER AND NOCIFENSIVE REFLEX THRESHOLD

Over the plasma thiopentone concentration range 0–30 μg ml^{-1} (0–115 μmol $litre^{-1}$), the measures of CNS drug effect, hEEG total power and 1/MWT, expressed as a percentage of control values, increased linearly (ANOVA, F=34, 22, df=7, and P=0.001 and 0.006 for hEEG and 1/MWT, respectively) with drug concentration. hEEG total power was consequently highly correlated with 1/MWT (Pearson product moment coefficient=0.862, P=0.006) (fig. 3).

Discussion

The results of this study showed that subanaesthetic concentrations of thiopentone enhanced hEEG power and reduced nocifensive reflex threshold responses in the same range of plasma concentrations. The pharmacodynamic profiles of these two measures of CNS effect were highly correlated, particularly in the concentration range 0–30 μg ml^{-1} (0–115 μmol $litre^{-1}$) (P=0.006). As the hEEG effects of thiopentone are thought to reflect the concentration of drug at the CNS effect site,[6,9] this finding suggests that nocifensive reflex thresholds are a valid measure of CNS effects for thiopentone. Nocifensive reflex thresholds provide a discrete measure of anaesthetic depth which can be used throughout the entire range of clinically relevant thiopentone concentrations. In contrast, the presence or absence of a withdrawal response to noxious stimulation evaluates the pharmacodynamic relationship at only one behavioural end-point.

Dundee[15] first reported that thiopentone enhanced the response to somatic pain in humans, an effect that was shown to occur also in rodents.[16] Subsequent studies have shown that nocifensive reflexes can be enhanced by a variety of anaesthetics[4,5,13] in a concentration-dependent, time-independent manner,[14] and that the reflex enhancement remains constant under pseudo-steady state conditions.[4,17] Our results agree with the findings of MacIver and colleagues[9] that hEEG amplitude and total power increased with plasma thiopentone concentrations of 15–20 μg ml^{-1} (57–77 μmol $litre^{-1}$). Taken together, these findings support a role for nocifensive reflex threshold measurements in the assessment of the CNS effects of thiopentone. Gustafsson and colleagues[18] have recently quantified the depth of thiopentone anaesthesia in the rat using quantal responses to a variety of stimuli over a large range of pseudo-steady state plasma thiopentone concentrations. The use of the nocifensive reflex threshold enabled us, in this study, to extend their findings through a more detailed examination of the pharmacodynamics of thiopentone within the lowest range of concentrations (0–30 μg ml^{-1} 0–115 μmol $litre^{-1}$).

Previous *in vitro* studies of field potential recordings in the rat hippocampal slice preparation have reported results similar to ours. MacIver and Roth[19] found that pentobarbitone 200–800 μmol $litre^{-1}$ had a biphasic stereospecific effect on excitatory synaptic responses in the hippocampus.

Potential confounding factors in the present study include the use of partial restraint, and the cardiorespiratory effects of thiopentone in spontaneously breathing animals. With the present model, we were previously unable to demonstrate any influence of partial restraint on nocifensive reflex thresholds.[3,14] Although the physiological effects of thiopentone in the later stages of study 1 could clearly have influenced the hEEG and nocifensive thresholds, our main focus was in the initial phase of the infusion, when plasma thiopentone concentrations were less than 30 μg ml^{-1} (113 μmol $litre^{-1}$). All of the animals had normal physiological variables during this phase of the study (table 1), and the shorter infusion strategy used in study 2 did not disturb any of the physiological variables that we measured.

In summary, the results of this study demonstrated the validity of nocifensive reflex thresholds to quantify anaesthetic depth with thiopentone in the plasma concentration range 0–30 μg ml^{-1} (0–115 μmol $litre^{-1}$). Although peak nociceptive effects occurred at slightly lower thiopentone concentrations than peak activation of hEEG, the changes in nocifensive reflex threshold correlated well with changes in total power in the hEEG.

Acknowledgements

Effect of extradural analgesia on the paradoxical arousal response of the electroencephalogram

S. KIYAMA AND J. TAKEDA

Summary

Despite widespread recognition of the potential role of the processed electroencephalogram (pEEG) as a monitor of depth of anaesthesia, few studies have examined the effects of surgical stimuli on the intraoperative pEEG. Two groups of gynaecological patients (*n*=10 in each group), with or without pre-incisional extradural analgesia, undergoing gynaecological laparotomy under nitrous oxide and isoflurane anaesthesia were monitored with routine haemodynamic observations and pEEG. Patients who received pre-incisional extradural analgesia showed no significant changes in pEEG variables during surgery (mean spectral edge frequency 95 percentile (SEF95) 13.3 (SD 1.4) Hz), whereas in all patients without pre-incisional extradural analgesia, a significant decrease in SEF95 was noted (6.5 (1.1) Hz after incision compared with a pre-incisional value of 12.5 (1.4) Hz) together with an increase in arterial pressure (paradoxical response). In the latter group, SEF95 and arterial pressure returned to pre-incisional values after extradural analgesia was established during operation. During emergence from anaesthesia, both groups showed a significant increase in SEF95 (25.7 (1.4) Hz). This study suggests that intraoperative pEEG arousal response was different from changes detected when anaesthesia was terminated at the end of surgery. Surgical stimuli in the absence of adequate analgesia induced a paradoxical arousal response. (*Br. J. Anaesth.* 1997; **79**: 750–753).

Monitoring, electroencephalography. Anaesthesia, depth. Anaesthetic techniques, extradural. Anaesthetics volatile, isoflurane.

The electroencephalogram (EEG) has been used to monitor depth of anaesthesia,[1 2] to titrate i.v. anaesthesia[3 4] or as an index of equipotency when comparing two different types of anaesthetics.[5] Although most previous studies have examined EEG changes while patients are anaesthetized[6] or awakening from anaesthesia,[7–9] few anaesthetists would have difficulty in recognizing whether and when their patients lose or regain consciousness. Therefore, the use of EEG monitoring during these periods may not be necessary. However, it is during the intraoperative period when the difficulty arises in assessing adequacy of anaesthesia, particularly in the presence of neuromuscular block.

Several previous studies identified a threshold value of EEG numerical descriptors to recognize transition from surgical anaesthesia to the pre-arousal state.[1 8] It is therefore tempting to consider that the EEG pattern of imminent arousal, that is a dominant shift to low-amplitude fast waves, also occurs when anaesthesia is inadequate to suppress autonomic responses to noxious stimuli. However, it has been suggested that the mechanisms of arousal during emergence from anaesthesia may differ from arousal reactions induced by noxious stimulation.[10] Consequently, if the EEG is to be used as a routine monitoring tool in the operating theatre, the effects of different anaesthetics and also those of surgical stimuli must be elucidated. There are only a few studies from the same group dealing with the effect of surgery *per se* on intraoperative EEG.[11 12] These investigations showed that in response to surgical incision, a pattern occurs consisting of slow waves with autonomic signs such as an increase in arterial pressure and heart rate,[11] and this response was termed "paradoxical" arousal. Although the underlying mechanisms of this paradoxical EEG response remain unclear, we have shown that pEEG variables returned to pre-incisional values after extradural analgesia.[13] These findings prompted this study, to clarify the effect of extradural analgesia on intraoperative EEG changes, by comparing two groups who received extradural analgesia either before or after surgical incision.

Patients and methods

After obtaining Institutional Review Board approval and verbal informed consent, we studied 20 female ASA I patients undergoing elective total abdominal hysterectomy, allocated randomly to one of two groups of 10 subjects each to receive extradural analgesia either before or after surgical incision.

Patients received ranitidine 150 mg by mouth the night before surgery and again on the morning of surgery. No other sedatives or analgesics were given. Approximately 500 ml of lactated Ringer's solution were infused i.v. before insertion of an extradural catheter. A lumbar extradural catheter was sited at the L2–3 or L3–4 interspace. In both groups, 3 ml of 1% lignocaine with adrenaline 1:200 000 were given via the catheter as a test dose. An additional dose of 1.5% plain lignocaine 20 ml was administered in the pre-incisional extradural group (group 1). Analgesia extending from T4 to the sacral dermatome was confirmed by pinprick before induction. The post-incisional extradural group (group 2) did not receive any further local anaesthetic before induction. Instead, 20 ml of 1.5% plain lignocaine were given immediately after the measurement point at 15 min after incision in group 2.

In both groups, general anaesthesia was induced with thiopentone 5 mg kg^{-1} i.v. followed by inhalation of 1.0% end-tidal isoflurane and nitrous oxide in oxygen (fresh gas flow 5 litre min^{-1}, $F\text{I}_{O_2}$ 0.4). Tracheal intubation was facilitated with vecuronium 0.1 mg kg^{-1} i.v. The lungs were ventilated to maintain end-tidal carbon dioxide concentration at 4.7–5.0 kPa and inhalation anaesthesia was continued as above for the first 30 min after the start of surgery. Anaesthetic gases and carbon dioxide were measured by an anaesthetic gas monitor (Capnomac Ultima, Datex, Helsinki, Finland). Patients were questioned for recall of intraoperative events in the immediate postoperative period and on the following day.

pEEG MEASUREMENT

The pEEG was monitored by a Dräger pEEG monitor (version 3.01; Dräger AG, Lübeck, Germany). Four disposable electrodes in the bilateral fronto-mastoid configuration at the F3-A1 and F4-A2 positions, according to the international 10–20 nomenclature system, and a reference electrode in the frontal midline, were attached using EEG paste (Elefix, Nihon Kohden Corp., Tokyo, Japan), as described previously.[14 15] Impedance of the electrodes were maintained at less than 5 kΩ during the study.

The EEG was recorded at a sampling rate of 128 Hz and an epoch length of 2 s. The raw EEG signal was processed using fast Fourier transform. Processed EEG descriptors, including SEF95, median frequency (MF) and relative power of the delta, theta, alpha and beta bands, and the raw EEG waveform were displayed and recorded on a PC-compatible computer (T100CS, Toshiba, Tokyo, Japan). The pEEG was monitored continuously from induction of anaesthesia to emergence. At the postoperative off-line pEEG analysis, the raw EEG was inspected to ensure that the analysed data were devoid of artefacts caused by the occasional use of surgical diathermy. Data for SEF95, MF and relative power of the four EEG bands were averaged over 10 consecutive artefact-free epochs at the following times: (1) 10 min after tracheal intubation and before incision; (2) 15 min after incision; (3) 30 min after incision; and (4) when patients opened their eyes in response to verbal stimuli.

STATISTICAL ANALYSIS

Patient characteristics were compared using the unpaired *t* test and the Mann–Whitney *U* test, where appropriate. Intra-group comparisons of mean arterial pressure, heart rate and pEEG variables at the four times were analysed using repeated measures analysis of variance (ANOVA). Significant differences found with ANOVA were confirmed by two-sided, paired *t* tests for comparisons over time within groups. Bonferroni's correction for multiple comparisons was applied. Inter-group comparison at each time was performed by unpaired *t* test. $P<0.05$ was considered significant. Statistical calculations were performed using InStat 2.03 for Macintosh (GraphPad Software, San Diego, CA, USA).

Results

The two groups were comparable in age, weight, height, duration of surgery, amount of crystalloid fluid used during anaesthesia and surgical blood loss (table 1). Patients in group 2 showed a significant increase in mean arterial pressure at 15 min after incision, whereas mean arterial pressure in group 1 decreased slightly at 15 and 30 min after incision (table 2). Arterial pressure decreased significantly after extradural analgesia in group 2. There were no significant changes in heart rate in the groups throughout the study.

There were no significant differences in intra-operative SEF95 and MF values compared with pre-incisional values in group 1. In contrast, all patients in group 2 showed a significant decrease in SEF95 and MF after surgical incision (table 3). The relative

power of the delta band increased significantly while those of the theta, alpha and beta bands decreased significantly at 15 min after incision. SEF95 and MF in these patients returned to pre-incisional value after extradural analgesia. In both groups there were significant increases in SEF95 and MF when patients opened their eyes at the end of surgery compared with intraoperative values. Inter-group differences in SEF95 and MF were significant only at 15 min after incision. A suppression–burst pattern of raw EEG was not observed in any patient throughout the study. At the postoperative interview, no patient reported intraoperative recall.

Discussion

This study is the first to have shown clearly that lack of analgesia is associated with a significant change in pEEG variables. The EEG is a measure of electrical activity, primarily of the cerebral cortex. Therefore, afferent noxious stimuli from the surgical field may be detected as EEG changes whereas effective extradural analgesia interrupts these ascending stimuli. The EEG showed a dominant shift to slow waves after surgical incision in all patients who did not receive pre-incisional extradural analgesia (group 2). This change was accompanied by a significant increase in mean arterial pressure suggesting that depth of anaesthesia was inadequate to suppress sympathetic responses. Therefore, this EEG change may be regarded as paradoxical arousal. In contrast, in patients who received pre-incisional extradural analgesia (group 1), there were no significant changes in pEEG variables, at least for the first 30 min after incision, compared with those before surgery. These results suggest that when analgesia is inadequate, the EEG shifts to low-frequency rather than high-frequency waves which characterize transition from surgical anaesthesia to the arousal state. One may argue that paradoxical arousal after skin incision in group 2 may have been caused by the haemodynamic changes themselves rather than by lack of analgesia. To clarify if haemodynamic changes influence the EEG, another study in which patients without pre-incisional extradural analgesia are given vasodilators or β antagonists to prevent cardiovascular responses after skin incision may be necessary.

Standard EEG monitoring of the international 10–20 system is not readily applicable to routine surgical patients. The EEG monitored using the fronto-mastoidal configuration in this study can be a reasonable compromise in daily clinical practice. However, because of the spatial heterogeneity of EEG activities,[12] it should be noted that the paradoxical arousal response may not be demonstrated clearly when the EEG is monitored in other electrode configurations.

Our findings support those of Bischoff and colleagues' previous report[11] on the paradoxical arousal response. First, in eight of their 10 urological patients, anaesthetized with isoflurane and nitrous oxide, EEG slowing was noted during surgical manipulation with an increase in arterial pressure during steady-state isoflurane anaesthesia with a concentration of only 0.6% during transabdominal urological procedures. This suggests that analgesia was likely to be inadequate when the paradoxical arousal response was recorded. Second, surgical stimuli during open urological and gynaecological procedures are considered to be similar, at least in the initial phase. Although the paradoxical arousal response was clearly identified in both of these procedures, it is not clear if this paradoxical phenomenon occurs in other types of surgery. Third, Bischoff and colleagues recorded the EEG for 20 min. It would be interesting to observe the EEG for longer while the extent of noxious surgical stimuli changes with time. In this study, it could be argued that even without extradural analgesia, this paradoxical response may have disappeared while patients were breathing nitrous oxide and 1.0% isoflurane. However, because of a significant increase in arterial pressure after incision in these patients, which most anaesthetists would treat by giving more analgesics or inhalation anaesthetics, it was considered unethical to maintain a relatively light level of anaesthesia deliberately beyond the

15-min observation period in paralysed patients. In group 1 patients, intraoperative SEF95 was maintained within a relatively narrow range at approximately 13 Hz, whereas in group 2 patients, SEF95 was approximately 12 Hz after extradural analgesia following the paradoxical arousal response. These findings are consistent with previous reports of SEF values during the maintenance phase of anaesthesia.[5,8,16] Although there were no cases of intraoperative awareness in either group, it is unclear if light general anaesthesia reflected by sympathetic hyperactivity and the pEEG paradoxical arousal response lead to intraoperative awareness if not treated correctly.

One of the problems when assessing the pEEG as a monitor of depth of anaesthesia is that a change in pEEG is dependent on the anaesthetic agent used. For example, previous studies on the EEG during sufentanil induction in cardiac patients have shown that the post-induction SEF95 value was much lower than that observed in the present study.[6,17]

A total i.v. technique or combination of light general anaesthesia and regional block enables titration of different components of anaesthesia, that is hypnosis and analgesia. This is advantageous if we can reliably distinguish which component needs to be adjusted in anaesthetized, paralysed patients. Taking into account the aforementioned limitations and our current knowledge of the EEG effects of various drugs and surgical stimuli, the pEEG may still be far from an ideal monitor of anaesthetic depth. However, with the current practice of balanced anaesthesia, it is noteworthy that the presence or absence of extradural analgesia can be recognized by the paradoxical arousal response after surgical incision. Therefore, adequacy of analgesia should also be considered when assessing the intraoperative pEEG.

Acknowledgements

We thank Dräger Japan Ltd for the loan of the pEEG monitor. We thank Dr Ryoichi Ochiai, Dr Koichi Tsuzaki and Dr Hiroshi Morisaki, Department of Anesthesiology, Keio University, School of Medicine, for their critical reading of the revised manuscript and invaluable comments. We are also grateful to Dr Tamotsu Yoshikawa, Department of Anaesthesia, Shizuoka Red Cross Hospital, for his help in the acquisition of the pEEG data.

Time-frequency spectral analysis of heart rate variability during induction of general anaesthesia

H.-H. HUANG, H.-L. CHAN, P.-L. LIN, C.-P. WU AND C.-H. HUANG

Summary

We have examined the spectral components of heart rate variability (HRV) during induction of anaesthesia with thiopentone, tracheal intubation and subsequent inhalation of isoflurane–nitrous oxide. Commonly used spectral analysis methods such as fast Fourier transformation or autoregressive modelling require stationary data and are not suitable for the rapidly changing HRV data in this period. An advanced spectral analysis method, time-frequency analysis, which can treat non-stationary data, was used in this study. Multiple spectra were generated to demonstrate the time-related spectral components of HRV. Mid-frequency power (MF, 0.08–0.15 Hz), high-frequency power (HF, 0.15–0.5 Hz) and MF/HF ratio at baseline, after induction (before intubation), immediately after intubation and during maintenance periods were calculated and compared. MF and HF powers decreased after induction and were reduced further in the maintenance period but MF/HF ratio remained unchanged after induction. Immediately after intubation MF and HF powers did not differ significantly from the immediate pre-intubation values, but MF/HF ratio did. (*Br. J. Anaesth.* 1997; **79**: 754–758).

Spectral analysis of heart rate variability (HRV) provides a non-invasive means of assessing the regulation of the autonomic nervous system.[1–4] The power spectrum of HRV is quantified usually by the spectral power within the frequency intervals of high frequency (HF, 0.15–0.5 Hz), mid frequency (MF, 0.08–0.15 Hz) and low frequency (LF, 0.02–0.08 Hz). HF power is related to respiratory effect and affected mainly by parasympathetic regulation. MF power is related to baroreflex activity and is controlled by both sympathetic and parasympathetic nervous systems. LF power is considered to have some relationship to thermoregulation or renin–angiotensin system functions.[1] Spectral analysis of HRV has been used in several clinical investigations, such as prediction of the prognosis of myocardial infarction patients[5 6] and assessment of autonomic status of diabetic patients.[7] Several recent reports have focused on the change in spectral components of HRV during anaesthesia by different methods.[8–13] In many of these studies, the power spectrum of HRV was calculated by fast Fourier transformation (FFT) or autoregressive modelling (AR).[14] However, the assumption of data stationarity cannot be met in some situations. During induction of general anaesthesia, rapid onset of anaesthetic action, effect of tracheal intubation and administration of inhalation agents cause rapid changes in autonomic activity in a short period of time. It is not feasible to obtain stable data in such a short time period for conventional spectral analysis methods under this circumstance. Few studies have investigated the continuous change in spectral components of HRV and the possible effects of the various events during anaesthesia.

Time-frequency spectral analysis is an advanced spectral analysis method[15] which can generate multiple spectra with time instead of a single spectrum for the whole data segment, as is the case with the FFT method. In addition, time-frequency spectral analysis based on the so called "quadratic time-frequency distribution" can provide good resolution in both time and frequency. It has been used widely for time-varying signal analysis in many applications and should be a suitable tool for studying the time-related spectral components of HRV during induction of anaesthesia.

In this study, time-frequency spectral analysis was used to obtain continuous spectral components of HRV during induction of general anaesthesia. The changes in the spectral components of HRV during different stages of anaesthesia were compared quantitatively.

Patients and methods

The study was approved by the institutional Ethics Committee and informed consent was obtained from all patients. We studied 30 adult patients, ASA I or II, undergoing various types of elective surgery. None had cardiovascular, pulmonary, neurological, diabetic or thyroid disease. No premedication was given before surgery. In the operating room, ECG, non-invasive arterial pressure and pulse oximetry were monitored (Hewlett Packard Model 78354A, Hewlett Packard Corp., Palo Alto, CA, USA), and concentrations of end-tidal carbon dioxide and anaesthetic agent were analysed using a gas analyser (Capnomac, Datex Corp., Finland). General anaesthesia was induced with thiopentone 5 mg kg^{-1}, fentanyl 2 $\mu g\ kg^{-1}$, droperidol 0.05 mg kg^{-1} and suxamethonium 2 mg kg^{-1}, followed by tracheal intubation. Anaesthesia was maintained with isoflurane and 50% nitrous oxide in oxygen. The concentration of isoflurane was initially 2% and maintained at 1% expiratory concentration after the wash-in phase. Neuromuscular block was maintained with atracurium after tracheal intubation. The lungs were ventilated mechanically at a rate of 10 bpm and tidal volume was set to maintain end-tidal carbon dioxide tension at 4.0–4.6 kPa.

DATA MANAGEMENT

ECG monitoring was started at least 5 min before induction of anaesthesia. ECG data were recorded and digitized onto a personal computer via analogue to digital conversion at a sampling rate of 500 Hz. The recording ended at approximately 20 min after tracheal intubation, before the start of surgery. The recorded data were used for off-line analysis. Detection of peaks of R waves and R-R interval sequence calculation were performed by software using threshold and slope detection combined with rejection of candidate peaks during estimated refractory periods. ECG waveforms were displayed on the screen with detected peaks marked, and visual verification and manual editing were performed. The cardiac tachogram, which indicates instantaneous heart rate along a time axis, was calculated from the R-R interval series and was re-sampled at a frequency of 2 Hz to obtain an even sampling sequence.[16] Before time-frequency analysis, the data sequence was de-trended by polynomial fitting. There are many methods in time-frequency analysis, and the smoothed pseudo Wigner–Ville distribution (SPWVD) was used in this study. The power spectrum based on SPWVD for a specific time is calculated by the data within a time interval before and after that specific time. The length of the interval is termed the "window length". The "correlation" is calculated at each time and summed by applying different weights to each time point. The weight decreases as the distance from the specific time increases. The result is transformed into frequency domain to obtain the power spectrum. The window length was 64 s in our study. The power spectra were generated at 4-s intervals. A technical appendix is attached to this article to provide a brief description of the algorithm used. Readers who are interested in more of the theory and implementation of SPWVD time-frequency analysis are referred to the literature.[15 17 18]

The spectral power of each spectrum was calculated at high frequency (HF, 0.15–0.5 Hz), mid frequency (MF, 0.08–0.15 Hz) and low frequency (LF, 0.02–0.08 Hz). Spectral powers were averaged in 2-min intervals for the following four periods: (1) baseline: from 2 min before induction to the start of induction; (2) pre-intubation or post-induction: from 2 min before tracheal intubation to the time of tracheal intubation. The patient was under the effect of the induction agents during this period; (3) immediately post-intubation: from the start of tracheal intubation to 2 min later; and (4) maintenance phase: from 10 min after tracheal intubation to 2 min later when the patient was already anaesthetized with isoflurane. The average spectral power of HRV in each period was performed on 30 consecutive spectra. In addition, the ratio of MF to HF power and mean heart rate in each period were also calculated.

All of the above ECG data management tasks, except manual verification of R wave peaks, were performed by software developed by ourselves with the computer language C (Borland C++ 3.1, Borland International Inc., CA, USA). Time-frequency analysis was performed by MATLAB (MathWorks Inc., MA, USA) on the Microsoft operating system Windows 3.1 (Microsoft Co., USA).

Comparisons of HRV data between the four periods were carried out using one-way repeated measures ANOVA with the Student–Neuman–Keuls test using the commercial package SigmaStat for Windows version 1.0 (Jandel Co., USA) run on the Microsoft operating system Windows 3.1. The significance level was set at $P<0.05$.

Results

The cardiac tachogram of one patient with a typical pattern is shown in figure 1A. The typical tachogram indicates a transient increase in heart rate during tracheal intubation and a gradual decrease after intubation. In figure 1B, the time-related spectral components of HRV are demonstrated by the three-dimensional plots of these spectra *vs* time. This is a typical time-frequency pattern of HRV with the change in spectral components in response to various events of anaesthesia. There are two points to be noted in the interpretation of such types of plots. (1) The frequency range less than 0.08 Hz, the lower limit of the MF range, is the low frequency (LF) range. For the short period used in this study, LF powers are generated mainly from the trends in mean heart rates and the powers are highest around the time of tracheal intubation because heart rate undergoes maximal change during this period. Although LF powers are usually higher than MF or HF powers, it was not our concern in this study and it should not be confused with MF or HF powers. (2) The spectral powers are calculated by integration of all amplitudes over the relative frequency ranges

Table 1 Heart rate variability (HRV) data for baseline, post-induction, immediate post-intubation and maintenance periods. All data are mean (SEM). *Significant *vs* baseline. †Significant *vs* post-induction; all $P<0.05$

	MF ((beat min^{-1})^2)	HF ((beat min^{-1})^2)	MF/HF	HR (beat min^{-1})
Baseline	2.10 (0.46)	1.23 (0.17)	1.57 (0.19)	85.2 (2.6)
Post-induction	1.13 (0.34)*	0.49 (0.08)*	1.95 (0.29)	88.5 (2.3)
Immediate post-intubation	0.99 (0.21)*	0.33 (0.05)*	3.14 (0.31)*†	99.2 (2.4)*†
Maintenance	0.07 (0.01)*†	0.13 (0.02)*†	0.62 (0.10)*†	72.8 (2.2)*†

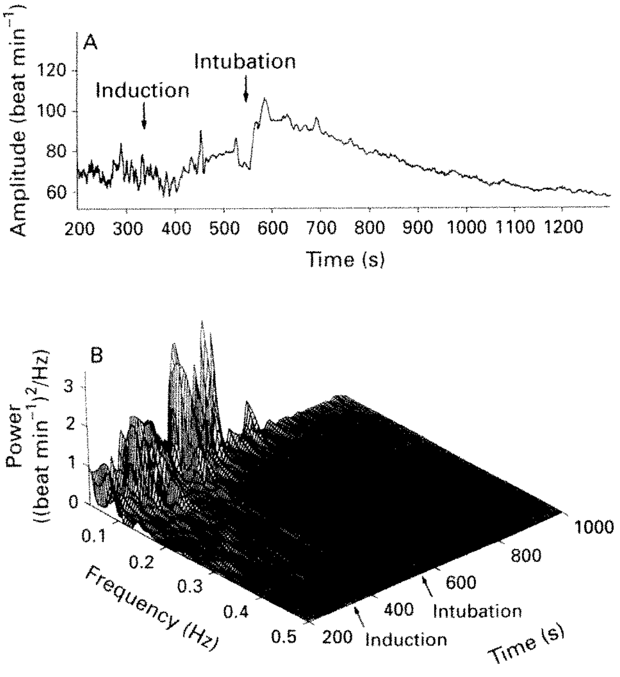

Figure 1 A: Cardiac tachogram of one patient with a typical pattern during induction of general anaesthesia. The unit of the tachogram in beat min^{-1}. B: Three-dimensional plot of multiple spectra generated by time-frequency analysis of heart rate variability (HRV) along the time axis. Note the frequency of MF power is 0.08–0.15 Hz and HF power is 0.15–0.5 Hz.

rather than counting only the highest peaks. The existence of one or several very high peaks in a single spectrum does not necessarily imply that the spectrum has higher powers than other spectra. This makes visual interpretation of the three-dimensional plots only qualitative rather than quantitative, and accurate powers must be calculated from the raw data.

In the three-dimensional plot in figure 1B, there are apparent spectral powers in MF and HF ranges before induction (baseline period). MF spectral power slowly decreased after the induction agents were given and tracheal intubation was performed. It decreased further after administration of inhalation agents. HF spectral power exhibited a similar trend as MF spectral power but it is not clear from the three-dimensional plots because of its low amplitude compared with MF spectral power.

Averaged MF and HF powers, MF/HF ratio and mean heart rate in different periods are shown in table 1 and figure 2. Both MF and HF powers decreased significantly after induction, remained at the same level immediately after tracheal intubation but decreased significantly in the maintenance phase. MF/HF ratio did not change significantly after induction. It increased immediately after tracheal intubation and decreased to a lower than baseline level in the maintenance phase during inhalation anaesthesia. Mean heart rate exhibited a similar trend as MF/HF ratio.

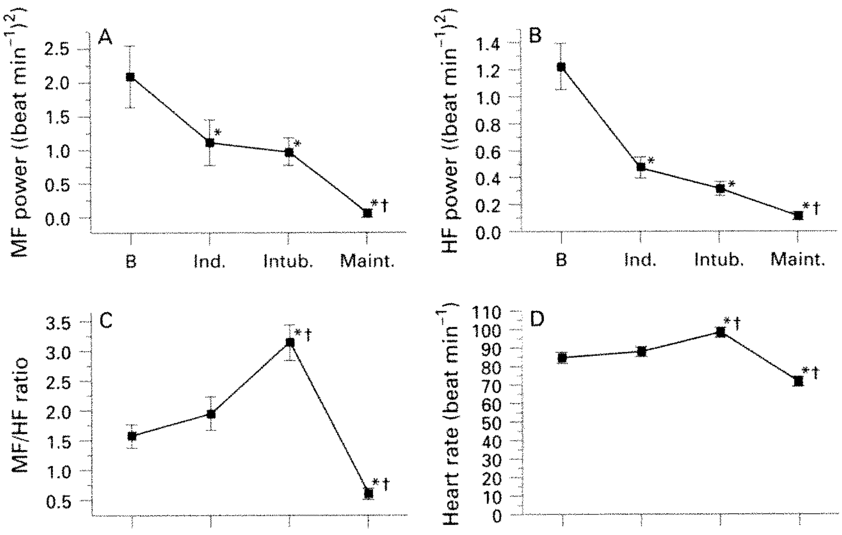

Figure 2 Plot of heart rate variability (HRV) data at baseline (B), after induction (Ind.), immediately after intubation (Intub.) and during the maintenance periods (Maint.). A=MF power, B=HF power, C=MF/HF ratio and D=mean heart rate. All data are mean (SEM). $P<0.05$ compared with: *baseline; †after induction.

Discussion

The spectral powers of MF and HF in heart rate signals are usually modulated by the sympathetic and parasympathetic nervous systems, and the ratio of MF to HF is often used as an index for autonomic nervous system balance. These components of spectral power of HRV can be used as indices of changes in autonomic activity during various types of anaesthesia and many researchers have focused on them. The commonly used methods in these investigations are FFT and AR modelling, which have the advantages of easy implementation and fast computation. The preliminary assumption of FFT or AR modelling is data stationarity, which implies that the data must be "stable" during the observation period.[14] When this condition is not met, the calculated spectral power is not reliable. The autonomic nervous system activity and HRV signals change rapidly during induction of anaesthesia, especially immediately before and after tracheal intubation. Spectral analysis by FFT or AR models is limited in interpreting data in this period because the assumption of data stationarity cannot be verified easily. Because of this, analysis of this transient period, which is most important for observation of the effect of tracheal intubation, remained largely ignored in previous studies.

In the time-frequency spectral analysis method, calculation of power spectra is based on correlation-like terms, which implicitly considers the temporal relationship of the data. This makes the assumption of data stationarity unnecessary. Analysis of the transient period immediately before and after tracheal intubation becomes possible and reliable. Based on time-frequency analysis, our study showed an increase in MF/HF ratio immediately after tracheal intubation. There was also a small but significant increase in heart rate but no significant increase in MF power. Because the MF/HF ratio is usually regarded as an index of the balance between the sympathetic and parasympathetic systems, these results suggest that autonomic nervous system balance is the main factor affected by tracheal intubation with induction agents. MF/HF ratio is more sensitive than MF power as an indicator of sympathetic nervous system activation. The increase in MF/HF ratio and mean heart rate immediately after intubation indicates that sympathetic nervous system activation after intubation was not blocked totally by the induction agents. Our result is similar to that of Hopf and colleagues who concluded that MF/HF ratio rather than MF power (LF in their article) reflects sympathetic activity during extradural anaesthesia.[19]

Because the time-frequency analysis method can generate multiple spectra continuously, we can also observe the change in HRV during different time segments in the induction phase. In our study, both MF and HF powers were reduced dramatically after administration of the induction agents. This confirms that the fluctuations in heart beat are suppressed by induction agents, as reported by others.[8–10] MF/HF ratio increased slightly but not significantly during induction which suggests that the balance of the autonomic nervous system was not altered to any great extent by the induction agents.

Several studies have demonstrated reductions in MF and HF powers by isoflurane.[11–13] In our study, MF and HF powers and MF/HF ratio in the maintenance phase were not only lower than those at baseline, but also lower than those in the post-induction phase. In the beginning of the maintenance phase, alteration of HRV could be the result of the combined effects of induction and inhalation agents. However, the data we used for statistical comparison were obtained 10 min after tracheal intubation and the pharmacological effect of the short-acting agents we used such as thiopentone may be very low. Hence, it is likely that the change in MF and HF powers in the maintenance phase was caused mainly by the inhalation agents. The effect of isoflurane on HRV is more profound than the combination of our i.v. induction agents. Ireland and colleagues have shown that HRV recovered promptly after patients could follow verbal commands during recovery from general anaesthesia.[20] There is little information on the duration of effect of thiopentone on HRV, and therefore we do not know if the effect on HRV disappears immediately or decreases after thiopentone redistributes.

FFT or AR modelling methods also suffer from the balance between temporal resolution and frequency resolution. In contrast, the time-frequency analysis method implicitly takes different data length for different frequency ranges in the signal and maintains both time and frequency resolution. Because of this and the advantages described above, the time-frequency method has been applied in many clinical fields,[21] including analysis of HRV in response to postural change and pharmacological effects,[17 22] and detection of brain activity in the EEG.[23 24] Our study is another example of the application of the time-frequency method. This new method not only increases temporal and spatial resolutions, but also opens some new windows. Time-frequency analysis should be very useful for other clinical studies on the interpretation of rapidly changing signals.

Appendix

The outline of the time-frequency analysis method used in our study is described below. Most of the descriptions make reference to the literature.[15 17 18] Interested readers should consult the original articles for further details.

The time-frequency analysis method is a class of signal processing algorithm which was developed under rigorous mathematical theory.[18] Wigner–Ville distribution (WVD) is one of the most commonly used in this class. The discrete version of the WVD of a time series $x(n)$ is defined as:

$$W(n,f)=\frac{1}{2}N\sum_{k=-N+1}^{N-1} x(n-k)x(n+k)\,e^{-2\pi kf/N}$$

Practically, n in the above formula is usually time and f=frequency, and the WVD is a function of time and frequency The term "distribution" has a similar meaning to "function".

The above formula is exactly the Fourier transformation of $x(n-k)x(n+k)$ on the variable k, so the WVD can be implemented by the FFT algorithm with only additional multiplications The major difference between the WVD and conventional discrete Fourier transformation (DFT) is that in WVD the correlation-like term $x(n-k)x(n+k)$ is transformed, rather than $x(n)$ itself in the DFT. If there is a rapid changing component in the original data, the time scale of the component is short and the correlation term decays rapidly to negligible values. This makes the effective time window length of a rapid changing component short. In contrast, a slow varying component keeps its correlation term non-negligible for a longer time. Thus the WVD implicitly uses different time window lengths for different frequencies in the data and keeps both time resolution and frequency resolution and can treat rapid time-varying signals.

The use of the correlation terms in the above formula could produce spurious spectral peaks and smearing in the time or frequency axis. Two modifications are made to solve the problems. The first is the use of a so called analytical signal, which is a signal without negative frequencies. Let $X(k)$ be the DFT of $x(n)$. We keep the positive frequency part of $X(k)$ and set its negative frequency part to zero:

$$Z(k)=2X(k)\ k>0,$$
$$Z(k)=X(k)\ k=0,$$
$$Z(k)=0\ k<0.$$

The inverse DFT of this $Z(k)$ is the analytical signal of the original signal $x(n)$, and is denoted $z(n)$. This $z(n)$ is used instead of $x(n)$ to obtain better results.

The second modification is the introduction of two window functions in the transformation:

$$W(n,f)=\frac{1}{2}N\sum_{k=-N+1}^{N-1}|h(k)|^2\left[\sum_{p=-M+1}^{M-1}g(p)z(n+p-k)z^*(n+p+k)\right]e^{-2\pi jkf/N}$$

The window $g[p]$ is termed the time smoothing window and the window $h[k]$ is the frequency smoothing window; z^* is the complex conjugate of z. The above formula is the final form of SPWVD. The time smoothing window and frequency smoothing window suppress spurious peaks and largely improve the quality of the spectrum.

The commonly used $g[p]$ is the unit rectangular window, or $g[p]=1$ (this is different from not using any window at all unless M is also set as 1). The commonly used $h[k]$ is a Gaussian window, defined as

$$h(k)=e^{-1/2[\alpha k/(N/2)]^2}\quad 0\leq|k|\leq N/2$$

In our study, the original data $x(n)$ is the R-R interval series. Analytical signal $z(n)$ is computed and used in the formula of SPWVD. Window functions of $g(p)=1$, $M=9$, and $\alpha=2.5$ and $N=64$ for Gaussian window $h(k)$ are used. For every specific n, the resulted $W(n,f)$ represents one single spectrum on the frequency axis f. The value of n is increased by 8 at every step, which means one spectrum is produced for every 4 s of data. In the three-dimensional plots, the time axis is n, the frequency axis is f and the values of $W(n,f)$ are plotted on the vertical axis. The spectral powers are calculated by the integration of $W(n,f)$ values.

Assessment of a new ventricular contractile index obtained with transoesophageal echocardiography before and after cardiopulmonary bypass in cardiac surgical patients

M. KIKURA, T. IKEDA, T. OHNUMA AND K. IKEDA

Summary

We have compared a new contractile index "left ventricular end-systolic wall stress–heart rate-corrected velocity of circumferential fibre shortening (vcfc)" with conventional contractile indices in 13 patients undergoing coronary artery bypass grafting. We generated the slopes of the "end-systolic wall stress–vcfc", "end-systolic wall stress–area" and "peak arterial pressure–area" relationships by altering arterial pressure before and after cardiopulmonary bypass (CPB). In all patients, significant correlations were obtained for end-systolic wall stress–area and peak arterial pressure–area relationships before and after CPB. In all patients, significant inverse linear correlations were obtained for the end-systolic wall stress–vcfc relationship before CPB; however, inverse linear correlation was absent in eight patients after CPB. It may be that the increased afterload had less influence on left ventricular systolic function after CPB as a possible mechanism of loss of the inverse linear correlation in the end-systolic wall stress–vcfc relationship. (*Br. J. Anaesth.* 1997; **79**: 759–765).

Key words
Surgery, cardiovascular. Heart, cardiopulmonary bypass. Heart, contractility. Monitoring, transoesophageal echocardiography.

The left ventricular pressure–volume relation developed by Suga and Sagawa has been used widely as a contractile index that is relatively insensitive to loading conditions,[1–3] and clinical use of this method has been reported for assessment of ventricular function in cardiac surgical patients.[4–6] The pressure–volume relationship requires invasive techniques to construct left ventricular pressure–volume loops and acute alteration of loading conditions by vena cava occlusion to obtain the end-systolic pressure–volume relationship. A relatively less invasive technique is available by examining the slope of the left ventricular end-systolic wall stress–dimension relationship by echocardiography. This relationship is based on the concept of the pressure–volume relationship, and is constructed by manipulating arterial pressure with vasoactive agents.[7 8] The end-systolic wall stress–dimension relationship correlates linearly within the physiological range and is sensitive to the inotropic state.[7 8]

Recently, a new echocardiographic assessment of contractility became available by examining the relationship between left ventricular end-systolic wall stress and heart rate-corrected velocity of circumferential fibre shortening (*v*cfc).[9] The slope of the end-systolic wall stress–*v*cfc relationship was found to be inversely linear over a wide physiological range, relatively independent of preload and sensitive to changes in contractility.[9 10] In the analysis of this relationship, an upward shift of the slope indicates an increased inotropic state, and a downward shift of the slope indicates a depressed contractile state.[9 10] Although the left ventricular end-systolic wall stress–*v*cfc relationship appears to be useful for assessment of ventricular contractility,[9–11] there is no information on this contractile index in cardiac surgical patients. Accordingly, we compared the left ventricular end-systolic wall stress–*v*cfc relationship with the conventional end-systolic wall stress–area and peak arterial pressure–area relationships before and after cardiopulmonary bypass (CPB) in patients undergoing coronary artery bypass grafting.

Patients and methods

After obtaining approval from the Department of Medical Ethics Committee and informed consent, we studied 13 patients undergoing elective primary coronary artery bypass grafting. Patients with an ejection fraction of less than 45%, previous history of myocardial infarction, regional wall motion abnormalities (diagnosed as severe hypokinesis, akinesis, dyskinesis or aneurysmal), valvular disease or congenital heart disease diagnosed by previous cardiac angiographic or echocardiographic examination were excluded. Also excluded were patients with atrial fibrillation or any oesophageal or gastric

pathology diagnosed as a contraindication to transoesophageal echocardiography.

Anaesthesia was induced with fentanyl 10 μg kg^{-1}, diazepam 0.15–0.2 mg kg^{-1} and vecuronium 0.15 mg kg^{-1}, and maintained with high-dose fentanyl (up to a total dose of 60 μg kg^{-1}) supplemented with benzodiazepines (diazepam or midazolam, or both) and 1–1.5% sevoflurane. Vecuronium was given to facilitate mechanical ventilation with 60% oxygen in air before CPB, or 100% oxygen after CPB. All patients were monitored with leads II and V5 of the electrocardiogram, and with radial and pulmonary artery catheters. After tracheal intubation, a gastroscope tipped with a 5-MHz multi-plane transoesophageal ultrasonic transducer (Hewlett Packard, Andover, MA, USA) was inserted into the oesophagus and positioned behind the left ventricle to obtain a short axis view at the level of the midpapillary muscles. The transducer was connected to an ultrasonograph (Sonos 1500, Hewlett Packard, Andover, MA, USA). While arterial pressure and heart rate were being recorded, two-dimensional echocardiograms were recorded on S-VHS videotapes by the attending anaesthetists (M. K., T. I. and T. O.) with at least 3 yr experience with intraoperative transoesophageal echocardiography.

After pericardiotomy, before aortic and right atrium cannulations, haemodynamic and echocardiographic data were obtained. Cardiac output was measured during apnoea at the end of expiration, in duplicate, by the thermodilution technique with 10 ml of iced saline at 0 °C using a pulmonary artery catheter (Opticath with Oximetrix 3 50130, Abbott Lab., North Chicago, IL, USA). Any cardiac output measurement significantly different (greater than ±10%) from its pair was excluded, and a repeat measurement was obtained. Peak systolic arterial pressure was adjusted to 90–110 mm Hg, as the baseline value, by continuous infusion of phenylephrine or prostaglandin E_1 (PGE_1), or both. To generate the slopes of the contractile indices, peak systolic arterial pressure, measured by a radial artery catheter, was increased to 30% of baseline by continuous infusion of phenylephrine 0.5–2.0 mg kg^{-1} min^{-1}, and then decreased to baseline by continuous infusion of PGE_1 0.05–0.2 mg kg^{-1} min^{-1}. Arterial pressure was recorded continuously on a multichannel recorder (78576A, Hewlett Packard, Andover, MA, USA) at a paper speed of 25 mm s^{-1}, and two-dimensional echocardiograms of the left ventricular short axis view with an electrocardiogram lead II were recorded on videotape while haemodynamic data were recorded simultaneously. We synchronized the video and the strip chart recorder to match the pressure values with the echocardiograms. All haemodynamic measurements were made during the expiratory pause phase of the ventilator cycle. Haemodynamic indices were calculated from pressure and cardiac output data with the use of standard formulae.[12]

CPB was conducted using a Cobe CML membrane oxygenator with a non-pulsatile flow of 2.2 litre min^{-1} m^{-2}. The system was primed with 1500 ml of balanced salt solution, 150 ml of 15% mannitol and hetastarch 500 ml. In all patients, hypothermia (25–28 °C) and aortic cross-clamping with cold hyperkalaemic cardioplegia were used. After the primary surgical operation, patients were warmed to a bladder temperature of 36.5–37 °C. The heart was defibrillated after cardiac reperfusion if sinus rhythm did not resume spontaneously. As a pressure gradient between central aortic pressure and radial artery pressure was often observed (sometimes more than 15–20 mm Hg) before weaning from CPB, femoral arterial pressure was monitored routinely to estimate central aortic pressure rather than radial artery pressure. A significant aortic-to-radial artery pressure gradient has been reported during and after CPB in a previous study[13] and femoral arterial pressure reproduces central aortic pressure more reliably than radial arterial pressure after CPB.[14] Patients were weaned from CPB using dopamine 5–8 μg kg^{-1} min^{-1} or nitroglycerin 0.5–1.0 μg kg^{-1} min^{-1}, or both, started before weaning to achieve a systolic arterial pressure >90 mm Hg and pulmonary capillary wedge pressure (PCWP) ≤18 mm Hg. Left ventricular preload was assessed by PCWP and left ventricular cavity area. After completion of CPB and protamine administration, measurements were repeated after aortic and right atrium decannulations but before sternal closure if patients were haemodynamically stable without new regional wall motion abnormalities. During manipulation of arterial pressure, the rates of i.v. volume infusion and continuous infusion of dopamine 5–8 μg kg^{-1} min^{-1} were kept constant, and bolus administration of i.v. anaesthetic drug was not performed. Sevoflurane was not used in any patient after weaning from CPB.

TRANSOESOPHAGEAL ECHOCARDIOGRAPHIC ANALYSIS

Echocardiographic analysis was performed by off-line tracings with the Hewlett Packard Sonos 1500 ultrasonograph system. Images were analysed by the authors (M. K., T. I. and T. O.) with previous published experience in the analysis of ventricular function.[11 15–17] We identified at least 10 data points at end-expiration for each regression line to generate the slopes of contractile indices in each patient. We traced the left ventricular short-axis endocardium at end-diastole to obtain end-diastolic area (EDA) and end-diastolic circumference (EDC). We traced endocardium and epicardium at end-systole to obtain end-systolic area (ESA) with papillary muscles included, end-systolic circumference of endocardium (ESC), and total area (At) enclosed by the left ventricular epicardium and right side of the septum. Leading-edge to leading-edge methods were used to trace the endocardium and epicardium.[18] Left ventricular ejection time (LVET) was determined using the number of frames (one every 33 ms) from end-diastole to end-systole. We identified ventricular end-diastole by the peak of the R wave and end-systole by the minimal left ventricular dimension. Fractional area change (FAC) and systolic circumferential fibre shortening (CFS) were determined as follows[19]:

$$\text{FAC}\ (\%) = 100 \times (\text{EDA} - \text{ESA})\ /\ \text{EDA}$$
$$\text{CFS}\ (\%) = 100 \times (\text{EDC} - \text{ESC})\ /\ \text{EDC}$$

We determined *vcfc* and end-systolic wall stress (index of afterload) as follows[9 20]:

$$vcfc = \text{CFS}\ (\%) \times (\text{RR})^{1/2}\ /\ (\text{LVET} \times 100)$$

where RR=interval between cardiac cycles, measured as the number of frames from the peak of the R wave to the next peak of the R wave, and EDC and ESC are measured in centimetres.

$$\text{End-systolic wall stress} = (1.35 \times P\text{sys} \times \text{ESA})/(\text{At} - \text{ESA})$$

where end-systolic wall stress is measured in g cm^{-2}, *P*sys=peak systolic arterial pressure (mm Hg), At and ESA are measured in cm^2 and 1.35 is a factor to convert mm Hg to g cm^{-2}. Each parameter of area in this equation was obtained with two-dimensional echocardiography. For practical convenience with M-mode echocardiogram, this original equation has been modified to one with endocardial diameter and wall thickness[20] However, two-dimensional echocardiography may involve less error to estimate wall stress than does M-mode echocardiogram. We used peak systolic arterial pressure in our calculation for end-systolic wall stress, based on the methods of Reichek and colleagues, indicating that end-systolic wall stress with peak systolic arterial pressure correlated well with invasively measured wall stress in a variety of clinical conditions.[7]

STATISTICAL ANALYSIS

One- and two-way analysis of variance followed by the Bonferroni multiple comparison test were used to compare changes in haemodynamic and echocardiographic data before and after CPB, and changes in those data during manipulation of arterial pressure.

In each patient, we plotted end-systolic wall stress on the *X*-axis against *vcfc* on the *Y*-axis, and plotted end-systolic area on the *X*-axis against end-systolic wall stress or peak arterial pressure on the *Y*-axis. At least 10 data points were plotted to generate each regression line in each patient. The linear regression equation was calculated by simple linear regression analysis with the least squares method. Statistical analysis was conducted using statistical software (Statview 4.0, Super ANOVA, Abacus Concept, Inc., Berkeley, CA, USA). $P<0.05$ was considered statistically significant, and all data are expressed as mean (SD).

Results

The heart was in sinus rhythm in all patients, and no new regional wall motion abnormalities, ST-segment changes or arrhythmias were observed. In these patients, a short axis view was obtained satisfactorily and echocardiographic analysis was performed. Three patients received two bypass grafts (one internal mammary artery and one saphenous vein), and 10 patients received three bypass grafts (one internal mammary artery and two saphenous veins). Patient data are given in table 1. Haemodynamic and echocardiographic variables before and after CPB are summarized in table 2. Heart rate and cardiac index after CPB were significantly higher than those before CPB, and systemic vascular resistance index after CPB was significantly lower than that before CPB. There was no significant difference in any other haemodynamic or echocardiographic variables between before and after CPB. Arterial pressure increased significantly from 107 (14)/52 (5) (72 (5)) to 142 (12)/65 (6) (90 (5)) mm Hg with phenylephrine administration, and then decreased to 107 (13)/53 (5) (73 (4)) mm Hg

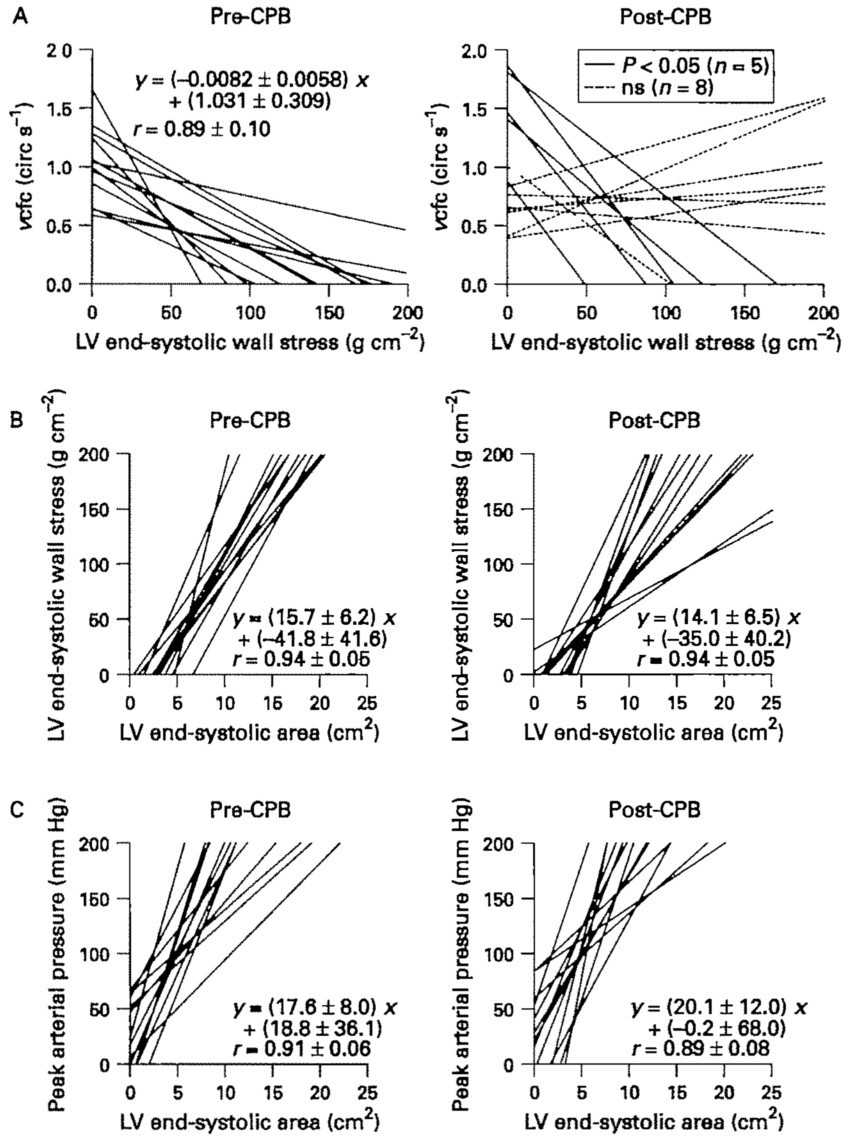

Figure 1 For the left ventricular (LV) end-systolic wall stress–heart rate-corrected velocity of circumferential fibre shortening (*vcfc*) relationship (A), significant inversely linear correlations were obtained in all patients before cardiopulmonary bypass (Pre-CPB), but the correlations were no longer inversely linear in eight patients (broken lines) after CPB (Post-CBP). For the LV end-systolic wall stress–area (B) and peak arterial pressure–area (C) relationships, significant linear correlations were obtained in all patients before and after CPB. ns=not significant.

with administration of PGE$_1$ before CPB, and increased significantly from 98 (8)/47 (5) (65 (4)) to 130 (11)/62 (5) (83 (5)) mm Hg after administration of phenylephrine, and then decreased to 101 (12)/50 (4) (67 (4)) mm Hg after administration of PGE$_1$ after CPB. During alteration of afterload, there was no significant change in EDA (index of left ventricular preload) before CPB (12.4 (3.3) cm^2 at baseline, 13.2 (3.8) cm^2 after administration of phenylephrine and 12.6 (3.7) cm^2 after PGE$_1$), or after CPB (11.9 (2.3) cm^2 at baseline, 13.1 (2.8) cm^2 after phenylephrine and 12.2 (2.5) cm^2 after PGE$_1$), and there was no significant difference in EDA in each state between before and after CPB. Manipulation of arterial pressure was accomplished within 15–20 min in all patients.

For the echocardiographic data, 292 data points were obtained for regression analysis; 146 data points before CPB and 146 data points after CPB. Regression equations, correlation coefficients, and lines between end-systolic wall stress and *vcfc*, between end-systolic wall stress and area, and between peak pressure and area are illustrated in figure 1. In all patients, the relationships between end-systolic wall stress and area, and between peak arterial pressure and area, showed significant linear correlations before and after CPB. Significant inverse linear correlations were obtained between end-systolic wall stress and *vcfc* before CPB in all patients, but the correlation was lost in eight patients after CPB. Between measurements taken before and after CPB, there was no significant difference in ventricular contractility measured by the slopes of the end-systolic wall stress–area and peak pressure–area relationships.

During alteration in arterial pressure, left ventricular end-systolic wall stress increased significantly after administration of phenylephrine and then returned to baseline after PGE$_1$ administration before and after CPB (fig. 2A). Between before and after

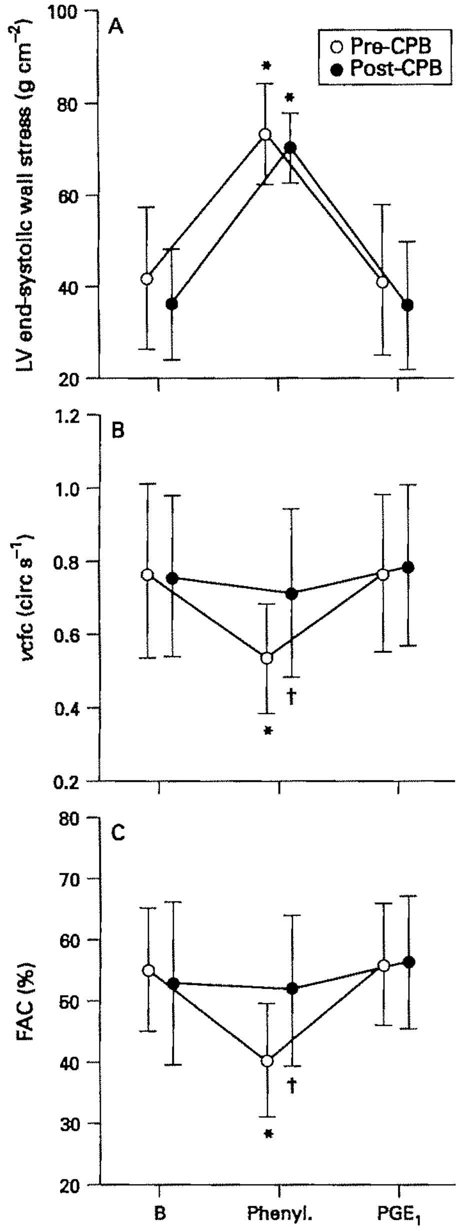

Figure 2 Changes in left ventricular (LV) end-systolic wall stress (A), heart rate-corrected velocity of circumferential fibre shortening (*vcfc*) (B) and fractional area change (FAC) (C) at baseline, after administration of phenylephrine (Phenyl.) and after administration of prostaglandin E_1 (PGE_1) before and after cardiopulmonary bypass (CPB). $P<0.05$ compared with: *baseline; †after CPB.

CPB, there was no significant difference in arterial pressure or end-systolic wall stress at baseline, after administration of phenylephrine or after administration of PGE_1. *vcfc* and FAC decreased significantly when end-systolic wall stress increased significantly before CPB, but there were no significant changes in *vcfc* or FAC after CPB (fig. 2B, 2C). Between patients with an inverse linear correlation ($n=5$) and those without an inverse linear correlation ($n=8$) in the end-systolic wall stress–*vcfc* relationship, there was no significant difference in aortic cross-clamp time (76 (15) *vs* 75 (15) min), CPB time (135 (35) *vs* 143 (21) min), dopamine requirements (7.2 (1.0) *vs* 7.5 (1.0) μg kg^{-1} min^{-1}), left ventricular EDA (11.9 (2.0) *vs* 12.3 (1.9) cm^2) or *vcfc* (0.748 (0.236) *vs* 0.726 (0.230) circ s^{-1}), respectively.

Discussion

The results of this study indicate that, in patients undergoing coronary artery bypass grafting, assessment of ventricular contractility is possible by examining the slope of the end-systolic wall stress–*vcfc* relationship and the end-systolic wall stress–area and peak arterial pressure–area relationships before CPB. After CPB, assessment of the contractile state is possible by measurements of the slope of the end-systolic wall stress–area and peak arterial pressure–area relationships, but not the slope of the end-systolic wall stress–*vcfc* relationship because of loss of the inverse linear correlation. It is possible that increased afterload had less influence on left ventricular systolic function after CPB as a possible mechanism for the loss of the inverse linear correlation between end-systolic wall stress and *vcfc*.

The end-systolic wall stress–*vcfc* relationship reported by Colan, Borow and Neumann[9] is based on the force–velocity relationship found in isolated human papillary muscle.[21] Although several studies have examined a contractile state by using the end-systolic wall stress–*vcfc* relationship,[9–11] there is no report on this contractile index in cardiac surgical patients. In this study, the significant influence of afterload on *vcfc* and FAC observed before CPB was not detected after CPB, and the significant inverse linear correlations between end-systolic wall stress and *vcfc* observed in all patients before CPB were lost after CPB. Although both *vcfc* and FAC are known to be dependent on left ventricular afterload,[9] the afterload dependence of *vcfc* and FAC observed in individual subjects before CPB was not necessarily reproducible after CPB in this study. A possible explanation could be that there was inotropic support with catecholamines during the period after CPB. Beta-receptor stimulation induced by administration of dopamine after CPB might have preserved left ventricular systolic function when afterload increased, although pure alpha adrenergic stimulation by phenylephrine caused significant reductions in ventricular function before CPB. Bolus administration of phenylephrine to patients with coronary artery disease has been shown to cause transient impairment of left ventricular function associated with a severe increase in afterload, while this transient reduction in ventricular function has not been observed in response to bolus administration of noradrenaline (alpha- and beta-receptor agonist).[22] The other possible explanation could be intrinsic beta-receptor stimulation induced by an increase in sympathetic nerve activity in the heart after CPB. An intense sympathomimetic stimulus to the heart was observed at the end of CPB in cardiac surgical patients,[23] and rewarming at the end of CPB markedly increased sympathetic nerve activity in animal experiments.[24]

The left ventricular end-systolic pressure–volume relationship has been established as a contractile index that is relatively insensitive to loading conditions.[1–3] Recently, Gorcsan and colleagues reported less invasive methods to construct pressure–volume loops during inferior vena caval occlusion by using automated echocardiographic measurements of left ventricular cavity area and femoral arterial pressure monitoring.[5 6] Their studies indicated that on-line pressure–area relationships may be clinically useful for estimating ventricular contractility in cardiac surgical patients. The slope of the left ventricular end-systolic wall stress–dimension relationship is also sensitive to the inotropic state.[7 8] The end-systolic wall stress–dimension relationship can be determined by manipulating arterial pressure with vasoactive agents, and is correlated linearly within the physiological range.[7 8] O'Kelly and colleagues reported that the slope of the end-systolic wall stress–dimension relationship obtained before surgical incision was useful for measuring ventricular contractility in patients undergoing coronary artery bypass grafting.[25] To our knowledge, our study is the first to examine if the end-systolic wall stress–dimension relationship is useful for assessment of a contractile state after weaning from CPB. In contrast with the end-systolic wall stress–*v*cfc relationship, our study indicated that the end-systolic wall stress–area and peak arterial pressure–area relationships were useful for assessment of contractile state both before and after CPB. The curvilinearity in a pressure–volume relation has been reported to produce negative values for the extrapolated area–axis intercepts derived from linear regression analysis.[26] The negative area–axis intercept in the peak arterial pressure–area and end-systolic wall stress–area relationships observed in this study might be attributable to such curvilinearity. Wall stress may be a better index of afterload than left ventricular pressure when left ventricular wall thickness is chronically altered, as in ventricular hypertrophy.[27]

We used PGE_1 to decrease arterial pressure. In a previous animal study, we showed that PGE_1 decreased preload and afterload during 10%, 20% and 30% decreases in mean arterial pressure, but had no inotropic action on myocardial contractility assessed by a load-independent contractile index.[16] PGE_1 did not induce significant change in right ventricular contractile state assessed by preload recruitable stroke work as a load-insensitive index in patients after pulmonary resection.[28] Changes in EDA by two-dimensional echocardiography are considered to reflect changes in end-diastolic volume, reflecting a change in LV preload.[29] The absence of significant change in EDA during alteration in afterload indicated that left ventricular preload was affected minimally by afterload manipulations caused by phenylephrine or PGE_1. The absence of significant difference in EDA before and after CPB indicated that left ventricular preload conditions were comparable between those states.

An automated border detection system using integrated backscatter imaging (Acoustic quantification, Hewlett Packard, Andover, MA, USA) is useful for real-time measurements of left ventricular cavity area and circumference by identifying ventricular endocardial–blood boundaries.[30] As determination of wall stress required a tracing of epicardium that was not currently available by automated border detection, time-consuming off-line analysis was necessary in this study.

In summary, determining the slope of the end-systolic wall stress–area and the peak pressure–area relationships permits assessment of ventricular contractility, whereas determining the slope of the end-systolic wall stress–*v*cfc relationship permits assessment of the contractile state before, but not after, CPB, because of the loss of inverse linear correlation.

Heat retention using passive systems during anaesthesia: comparison of two plastic wraps, one with reflective properties†

S. DEACOCK AND A. HOLDCROFT

Summary

Hypothermia during prolonged surgery may be prevented by active and passive warming methods. We have compared randomly two types of occlusive body wraps in groups of 20 patients. One wrap had additional reflective properties which, by reducing radiative in addition to convective and evaporative heat loss, was expected to improve heat conservation. Patients were studied during hepatopancreatobiliary surgery and both groups were similar in characteristics. Skin and core body temperatures increased and core temperature exceeded 37 °C in 40% of patients in both groups. This continuous increase in temperature was unexpected and the observed heat gain may have been stimulated endogenously by the type of surgery rather than that supplied externally. Overall, mean hourly heat gain was similar in both groups: 71 (SD 28) kJ h^{-1} in the reflective group and 67 (33) kJ h^{-1} in the other group. (*Br. J. Anaesth.* 1997; **79**: 766–769).

Key words

Temperature, body. Temperature, monitoring. Equipment, warming devices. Monitoring, temperature.

Core body temperature in conscious humans is regulated precisely by an intrinsic system with central hypothalamic control and a behavioural system which allows extremes of temperature to be tolerated without hypothermia or hyperthermia developing. Heat is tolerated less than cold because denaturation of proteins occurs at core body temperatures greater than 42 °C whereas a similar decrease in body temperature usually causes reversible changes. Anaesthesia and surgery prevent behavioural responses and alter the homeostatic response to temperature variations by changes in both the cardiovascular effector system and central and peripheral nervous system control.[1] Perioperative core body temperatures therefore often decrease below normal. This iatrogenic hypothermia is associated with numerous postoperative complications of which the most important are shivering, which induces hypoxaemia,[2] and prolongation of drug action.[3] These problems are more common during prolonged surgery, especially when major blood loss occurs and patients are malnourished. In severely ill patients, additional hazards of hypothermia include impaired coagulation[4] and negative postoperative nitrogen balance.[5]

Although the hypothermic effects of anaesthesia on temperature homeostasis may be unavoidable, the physical factors which contribute to heat loss and gain may be controlled. Many different active and passive systems provide heat gain and also prevent heat loss. Body cavity exposure during surgery with resultant evaporative heat loss may not be controllable, but it is possible with access to the body for heat transfer by conduction, convection and radiation. Radiation is considered to be the major source of heat loss in an awake, resting individual. It becomes a significant factor for heat loss during surgery if the patient is uncovered in cold surroundings or is vasodilated.[6] Radiative heat losses can be restricted by the use of metallized plastic foil, such as space blankets, but the increased risk of burns and electric shock has limited their use in the operating theatre, except for specially designed plastic wraps with punctate metal fragments on a plastic backing which do not conduct electricity (Thermadrape; Vital Signs, Sussex, UK).

It was hypothesized that the combination of plastic wraps incorporating a reflective surface to prevent radiative heat loss should provide more heat retention than a simple plastic bag during major surgery. Reflective wraps in volunteers not undergoing surgery or anaesthesia provided better insulation than plastic bags,[7] but reflective blankets during surgery required a large surface area to be covered in order to significantly increase core temperature.[8] It was considered that for ethical reasons relating to the complications of inducing mild hypothermia, unnecessary heat loss should be prevented in this study. Therefore, reflective and ordinary plastic bags were used with standardized heat retentive procedures. Such procedures were known to reduce but not prevent heat loss during major surgery.

Patients and methods

After obtaining Ethics Committee approval and informed verbal consent, we studied 40 patients undergoing hepatopancreatobiliary surgery. Patients were allocated by random number tables before the study to one of two groups: in one group the Thermadrape wrap was used and in the other, large, thin transparent plastic bags were used. These wraps covered all limbs, except for i.v. sites. Before anaesthesia all patients were normothermic, and antibiotics were administered routinely for prophylaxis when anaesthesia commenced. The anaesthetic technique was standardized using thiopentone, fentanyl and vecuronium in appropriate doses. After tracheal intubation, anaesthesia was maintained with intermittent positive pressure ventilation of the lungs via a heat and moisture exchanger (Pall) using isoflurane and nitrous oxide in oxygen. Additional analgesia was provided with fentanyl 1 μg kg^{-1} h^{-1} either i.v. or combined with 0.1% bupivacaine and administered extradurally, as indicated clinically. Blood replacement during surgery was given to prevent hypotension and to maintain a packed cell volume of 30–35%. Whole or plasma-reduced blood and albumin solution (4.5% HAS) were infused on a volume replacement basis. The main replacement solution was crystalloid, and Haemaccel was administered as indicated. Urine output was measured every 30 min.

Patients were transferred to theatre from the anaesthetic room, after insertion of invasive monitors for measurement of arterial and venous blood pressures. Active conduction of heat was standardized: a warm air mattress at 39.5 °C was positioned under the patient, fluids were warmed to 36 °C and the ambient theatre temperature was maintained at 21–24 °C. Before surgery the temperature monitors and limb wraps were positioned. Core temperature was measured in the nasopharynx. Four skin temperatures were recorded from the nipple, upper outer arm, mid-dorsal thigh and lateral surface of the mid-calf to provide a calculation for mean skin temperature applicable to anaesthesia.[9] The instrument used was an Ellab PD85U thermometer (Ellab Instruments, Copenhagen). Mean body temperature was measured from core and mean skin temperatures, and from this, using an average value for the specific heat of tissues and the patient's body weight, total body heat was calculated.[10] Hourly temperature measurements were started just before surgery and calculations of total body heat were made every hour during surgery. Change in total body heat was measured from the first record. The relative humidity inside the wraps was measured with a humidity meter (HM humidity and temperature meter, Vaisala, Finland).

A mixed model analysis of variance (using the statistical package, Genstat; NAG Ltd, Oxford, UK) was used to compare the relationship between change in body heat with time in patients wrapped in Thermadrape or plastic bags. The normality assumption of residuals from the ANOVA was checked using the Watson test, and Bartlett's test was used to test the equal variance assumption. In two patients in each group, core body temperature increased to greater than 37.5 °C during surgery. At this time active heating was discontinued and data after this intervention were not included in the statistical analysis.

Results

The two groups were similar in age, body mass index (kg m^{-2}) and duration of operation (table 1). Patient age, height, weight or body mass index did not correlate with the rate of heat gain. Three patients in the Thermadrape group and two in the plastic bag group received extradural infusions. Mean blood loss measured on swabs was 1620 (range 720–13674) ml in the Thermadrape group and 1786 (571–3893) ml in the plastic group.

Mean core temperatures before surgery were 35.8 and 35.8 °C, which increased to 37.3 and 37.2 °C in those patients studied after 7 h of surgery (an increase of 1.5 and 1.4 °C) in the Thermadrape and plastic groups, respectively. Individual core temperatures indicated that 40% of patients in both groups exceeded a value of 37 °C during surgery. Figure 1 shows mean hourly measurements of core body temperature. As the mean duration of surgery was approximately 5 h, confidence intervals became wider after this time.

Mean heat gain was 71 (SD 28) kJ h^{-1} and 67 (33) kJ h^{-1} in the Thermadrape and plastic bag groups,

Table 1 Patients characteristics and duration of operation in the two groups of patients, one wrapped in Thermadrape and the other in plastic bags (mean (SD or range))

	Thermadrape (n=20)	Plastic (n=20)
Age (yr)	52 (28–71)	51 (26–73)
Weight (kg)	72 (11)	72 (11)
Height (m)	1.7 (0.8)	1.7 (0 1)
BMI (kg m^{-2})	25 (3 8)	25 (2.8)
Duration of operation(min)	311 (122)	284 (92)

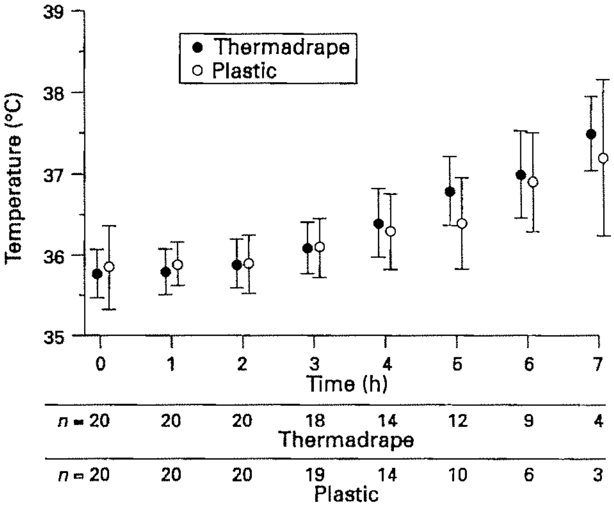

Figure 1 Relationship between core body temperature and duration of surgery for the Thermadrape and plastic bag groups, with hourly values of temperature measured as mean (95% confidence intervals). The number of patients in each group per hour is shown for each full hour of surgery.

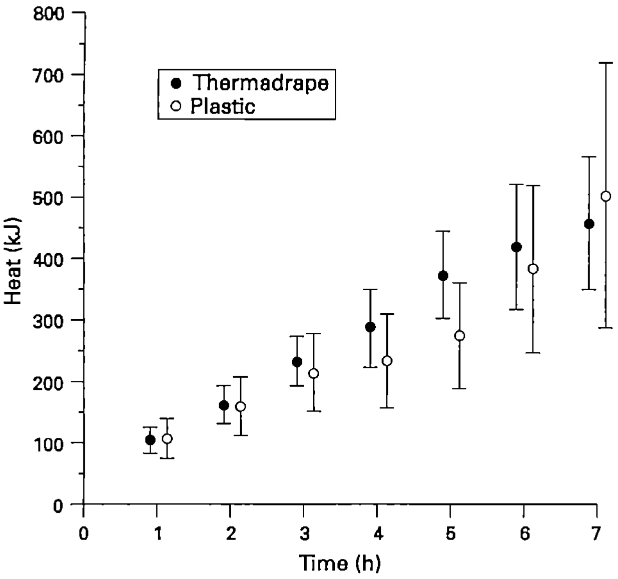

Figure 2 Relationship between cumulative increase in body heat (i.e. difference between heat stored in the patient before surgery and body heat calculated hourly) and duration of surgery for the Thermadrape and plastic bag groups, measured as mean (95% confidence intervals).

respectively. Cumulative mean hourly increases in body heat during surgery are shown in figure 2. There was no significant difference between the two groups for each hour. However, the mixed model analysis of variance demonstrated that there was a significant difference in the relationship between heat gain and time with the two wraps. It appears from figure 2 that heat gain was similar for the first 3 h but then twice as much heat was gained in the next 2 h in the Thermadrape group. This relationship then changed so that patients in plastic wraps gained more than twice as much body heat as in the other group. However, the number of patients studied after 5 h became too few to allow statistical comparison. There were no differences in relative humidity within the wraps during the study; the internal environment inside all wraps reached full saturation within minutes and this was maintained throughout surgery.

Discussion

We expected that hypothermia would be prevented in one of the groups, but instead uninterrupted heat gain was observed in both groups. On induction of anaesthesia, redistribution of body heat normally occurs from the warm core to the cooler peripheral tissues which is followed by a slow, almost linear, decrease in core temperature resulting from heat loss exceeding production. After approximately 3–4 h of anaesthesia, core temperature has been observed to plateau as a result of thermoregulatory vasoconstriction sequestering metabolic heat in the core thermal compartment.[11] General anaesthesia may alter cardiovascular effector control systems of temperature regulation, and in addition may blunt the nervous system response to deviations from normal body temperatures.[1] Widening of the set points at which effector responses for heat gain and loss are generated has been described in patients not undergoing surgery.[12] In effect, this implies that a higher or lower temperature must be reached in order to switch on the respective regulatory response.

No patient was pyrexial before surgery and patients with treated infections were not recruited. This study was undertaken in patients who had major upper abdominal surgery, some of whom had biliary stents with the potential to act as a nidus for infection and the development of septicaemia. Surgery itself induced major haemorrhage but even with blood warmers set at 36 °C this would not have increased body temperature above normal. Another contributing factor to the universal heat gain could have been the thermogenic effects of infused fluids such as albumin solution[13] but it was considered that the amounts used as replacement for blood loss would be inadequate to provide the additional heat generated.

The inclusion of five of 40 patients with extradural infusions requires comment because extradural anaesthesia with segmental block is known to induce peripheral vasodilatation with associated heat loss during surgery[14] or in volunteers.[15] However, a low-dose bupivacaine extradural infusion was used in combination with an opioid for analgesia and a dense segmental block was not achieved. If any effect on body heat was expected, it should have reduced the heat gain observed.

The physical size of the patient did not correlate with the rate of heat gain. This finding did not confirm those in volunteers using insulated drapes whereby the amount of skin covered was an important factor.[7] It was expected that patients with a large surface area related to the limbs would have a different rate of heat flux than those with small limbs, particularly as the wraps were applied in these areas. Body weight, height and body mass index showed no relationship with heat gain.

If heat loss occurs mainly by radiation during anaesthesia and surgery, then the reflective wraps should have prevented major heat loss and this group should have gained heat faster. As this did not occur, radiation as a source of heat loss during surgery may not be a major factor. However, after 3 h of surgery the increase in body heat varied between the plastic and reflective wraps. This could indicate a different response to heat dissipation between the two groups and may account for the comfort felt when wearing the reflective wrap. The relative humidity inside both wraps reached 100% within minutes and hence both wraps effectively prevented evaporative heat loss. The reflective wraps also contained a cotton lining and were produced originally as a comfortable garment to wear. This additional absorptive quality of the reflective wrap may have assisted thermoregulatory evaporation to proceed when body temperature exceeded normal limits.

It was disturbing to observe an increase in core body temperature above normal in both groups as additional methods of active heat transfer could have been used clinically in addition to the ones chosen. Core temperature measurement is usually the only site of body temperature measurement during clinical anaesthesia. However, an increase in total body heat cannot be assumed unless peripheral temperatures are also increased, because in major surgery vasoconstriction may occur with a reduction in blood flow to the skin such that body heat is diverted from the periphery to the centre. The result is that total body heat can decrease while core temperature increases. This may accompany haemorrhagic shock, but was not observed during this study despite major haemorrhage.

Both systems of wraps for heat retention during surgery were effective in preventing heat loss when combined with routinely used methods. An increase in heat gain above heat loss was recorded in all patients during prolonged surgery. This emphasizes the importance of temperature monitoring when active and passive warming measures are used.

Comparison of the accuracy of the lithium dilution technique with the thermodilution technique for measurement of cardiac output

T. Kurita, K. Morita, S. Kato, M. Kikura, M. Horie and K. Ikeda

Summary

A new indicator dilution technique for measurement of cardiac output is described. Lithium chloride is injected via a central venous catheter and its dilution curve measured in arterial blood using a lithium-selective electrode. We assessed the lithium dilution cardiac output measurement (LiDCO) and a conventional thermodilution cardiac output measurement (ThDCO) by comparing the results of both with cardiac output determined by electromagnetic flowmetry (EMCO) under controlled laboratory conditions in 10 swine. They were monitored with a pulmonary artery catheter, femoral artery catheter and electromagnetic flowmeter placed around the ascending aorta. LiDCO, ThDCO and EMCO measurements were determined at baseline, in a hyperdynamic state produced by administration of dobutamine, at a second baseline and finally in a hypodynamic state induced by propranolol during deep anaesthesia. Data were analysed by linear regression analysis and the comparison method described by Bland and Altman; bias and precision of both LiDCO and ThDCO compared with EMCO were calculated by the method of Sheiner and Beal. The correlation coefficient between LiDCO and EMCO (0.95) was higher than that between ThDCO and EMCO (0.87). The precision value of LiDCO (0.04) was significantly less (i.e. better) than that of ThDCO (0.09). The results of this study indicated that LiDCO was more reliable compared with conventional ThDCO. (*Br. J. Anaesth.* 1997; **79**: 770–775).

The thermodilution technique using a pulmonary artery catheter has been widely used clinically for measurement of cardiac output. With this technique, insertion of a pulmonary artery catheter involves an invasive procedure associated with several risks and complications.[1–3] A recent report indicated that pulmonary artery catheterization is associated with an increase in mortality and cost of care.[4] Errors in measurement may be introduced by rewarming of the injectate caused by handling before injection and by heat transfer during passage through the pulmonary artery catheter.[5–9] Thermodilution may overestimate cardiac output during a low cardiac output state, probably because of excessive heat exchange secondary to slow passage of injectate.[10 11] A less invasive method is available using a lithium dilution technique that uses lithium chloride as the indicator. A preliminary clinical study of this technique has been reported by Linton, Band and Haire.[12] Lithium chloride, injected into the right atrium via a central venous catheter, is measured by a sensor attached to the peripheral arterial catheter, and cardiac output can be measured without a pulmonary artery catheter. Lithium does not normally exist in the human body, does not bind to plasma or tissue proteins and is excreted almost entirely in urine.[13–15] There have been no studies comparing the lithium dilution technique with the thermodilution technique under controlled hypodynamic or hyperdynamic laboratory conditions. Accordingly, we assessed the reliability of lithium dilution and thermodilution techniques by comparing both with cardiac output determined by electromagnetic flowmetry under controlled hypodynamic and hyperdynamic states.

Materials and methods

EXPERIMENTAL PROCEDURE

After obtaining approval from the Institutional Ethics Committee, we studied 10 swine (body weight 10–15.5 kg). After administration of ketamine 5–7 mg kg^{-1} i.m., general anaesthesia was induced by inhalation of 4% sevoflurane in oxygen 5 litre min^{-1} using a standard animal mask. After induction, the trachea was intubated with a cuffed tracheal tube, and anaesthesia was maintained with 3% end-tidal sevoflurane and 100% oxygen with mechanical ventilation (Harvard apparatus dual phase control pump, GI3, South Natick, MA, USA). A peripheral venous cannula (20-gauge) was

inserted in the dorsal ear vein and lactated Ringer's solution was infused at a rate of 10 ml kg^{-1} h^{-1}. After induction, vecuronium or pancuronium was administered. End-tidal carbon dioxide was maintained at 4.7–5.3 kPa. Lead II of the electrocardiogram (ECG) was monitored with subcutaneous electrodes introduced into the legs. After median sternotomy and pericardiotomy, the probe of an electromagnetic flowmeter (Electromagnetic blood flowmeter, MFV3200, Nihon Kohden, Tokyo, Japan) was placed around the ascending aorta for continuous measurement of cardiac output. The probe attachment size was varied in order to fit the diameter of each particular aorta (FB120T, FB130T, FB140T, FB150T, FB160T, lumen diameter ranges 12–16 mm, Nihon Kohden). The electromagnetic flowmeter system was calibrated initially and before each change in haemodynamic state. The position of the probe of the electromagnetic flowmeter was checked after the swine was killed with potassium chloride i.v. under deep anaesthesia with 5% inspired sevoflurane.

A pulmonary artery catheter (5 F, 4 lumen, Nihon Kohden) was inserted into the right jugular vein, and a double-lumen catheter (16–18-gauge) was placed in the femoral artery. Arterial pressure was monitored via one lumen of the femoral artery catheter, and blood samples were obtained from the other lumen for measurement of plasma concentrations of lithium. Heparin 100 u. kg^{-1} was administrated in order to avoid blood clotting on the membrane surface of the lithium sensors, thus avoiding deterioration of the sensors. By warming with heating lamps, blood temperature of the swine was maintained in the range 36.5–37.5 °C. In all experiments it took less than 1.5 h from induction of anaesthesia to the first baseline measurements. After baseline measurements were obtained, haemodynamic status was changed from baseline to a hyperdynamic state (20–40% increase in cardiac output monitored with EMCO) by continuous infusion of dobutamine at a rate of 10 μg kg^{-1} min^{-1}, and then returned to baseline. Next, the status was changed from baseline to a hypodynamic state (20–40% decrease in cardiac output) by administration of propranolol 0.5–2.0 mg and increase in end-tidal sevoflurane concentration to 4–5%. After obtaining haemodynamic stability for at least 10 min, cardiac output was measured. ThDCO was determined by a thermodilution computer (Cardiac Output Computer, MTC6210, Nihon Kohden) using 5 ml of ice-cold 5% glucose injected into the right atrium. During apnoea at the end of expiration, indicators for LiDCO and ThDCO were administered by the same person. During measurement of cardiac output, we maintained the i.v. infusion rate constant. Values of EMCO were recorded when the indicators were injected. Measurement of cardiac output was duplicated, and two paired measurements of cardiac output were made in each animal under each haemodynamic condition. Any cardiac output measurement significantly different (greater than ±10%) from its pair was excluded, and a repeat measurement was obtained.

LITHIUM DILUTION CARDIAC OUTPUT MEASUREMENT

A prototype LiDCO measurement system was used (LiDCO, Ltd., London, UK). The lithium sensor consists of a flow-through cell containing a lithium-selective electrode developed for this use.[12] The indicator is lithium chloride 0.15 mol $litre^{-1}$, prepared in glass ampoules by the pharmacy at St Thomas's Hospital (London, UK). The voltage from the sensor is logarithmically related to plasma lithium concentration and is recorded via an electrically isolated preamplifier and analogue to digital converter by a Macintosh computer (PowerBook 5300CS, Apple Computer, Cupertino, CA, USA). Before they were used the sensors were calibrated by exposure to saline and then to a solution of lithium chloride 1 mmol $litre^{-1}$ in saline and recording the change in voltage. A roller pump (CP-136, Nissho Corporation, Osaka, Japan) was used to regulate blood flow from the femoral arterial catheter via the flow-through cell to 4 ml min^{-1} until a stable baseline voltage was recorded. Then, during apnoea at the end of expiration, 0.67 ml of a lithium chloride solution (0.15 mol $litre^{-1}$) was injected (dose=0.1 mmol) as a bolus into the right atrium via the atrial port of the pulmonary artery catheter. The same investigator performed all injections. To ensure that the injection bolus dose was exactly 0.67 ml, the deadspace of this catheter (0.39 ml) had previously been filled with more than 0.4 ml of lithium chloride solution until a small amount of indicator leakage had come out from the tip of the catheter, and had a small peak appeared on the recording curve of the concentration–time course. The primary circulation curve was discriminated from the secondary (or recirculation) curve by the method of Linton, Linton and Band, based on the theory of using a log-normal analysis to determine the integral of the primary curve.[16] Cardiac output was then calculated using the following formula by Linton, Band and Haire[12]:

$$\text{Cardiac output (litre min}^{-1}) = [\text{dose of lithium chloride (mmol)} \times 60] \,/\, [\text{area under curve (mmol litre}^{-1}\text{ s)} \times (1-\text{PCV})]$$

where area under the curve=the integral of the primary curve and PCV=packed cell volume. Division by (1−PCV) converts plasma flow to blood flow as lithium is distributed only in the plasma fraction of blood. PCV was measured as the value of haematocrit (Kubota Hematocrit KH-120A, Tokyo, Japan) before cardiac output measurement in each haemodynamic state.

STATISTICAL ANALYSIS

The linear regression equations between ThDCO and EMCO, and between LiDCO and EMCO were calculated by simple linear regression analysis using the least squares method. As recommended by Bland and Altman,[17] the difference (ThDCO−EMCO) compared with (ThDCO+EMCO)/2, and the difference (LiDCO−EMCO) compared with (LiDCO+EMCO)/2 were plotted and means (SD) of the differences were calculated. The predictive performance test described by Sheiner and Beal[18] was performed to evaluate statistical significance of the bias (mean prediction error by which ThDCO or LiDCO overestimates or underestimates EMCO) and precision (mean squared prediction error by which ThDCO or LiDCO overestimates or underestimates EMCO) values between two different dilution techniques. One-way analysis of variance followed by the Bonferroni multiple comparison test were used to compare the changes in cardiac output at each haemodynamic state. $P<0.05$ was considered statistically significant, and results are expressed as mean (SD).

Results

The value of EMCO obtained at baseline (1.41 (0.49) litre min^{-1}) was significantly lower than that in the hyperdynamic state (1.74 (0.47) litre min^{-1}), and was significantly higher than that in the hypodynamic state (0.93 (0.43) litre min^{-1}). There was no significant difference between the value of EMCO obtained at baseline (1.41 (0.49) litre min^{-1}) and that obtained at the second baseline (1.36 (0.53) litre min^{-1}). Three aberrant LiDCO readings and 20 ThDCO readings were rejected to obtain 80 readings, respectively. The correlations between ThDCO and EMCO, and between LiDCO and EMCO are shown in figure 1. The correlation

	Baseline 1	Hyperdynamic state	Baseline 2	Hypodynamic state	All data
ThDCO	−0.03, 0.06	0.04, 0.17	0.09, 0.07	0.03, 0.08	0.03, 0.09
LiDCO	0.10*, 0.03	0.01, 0.02†	0.18, 0.06	0.17, 0.06	0.11*, 0.04†

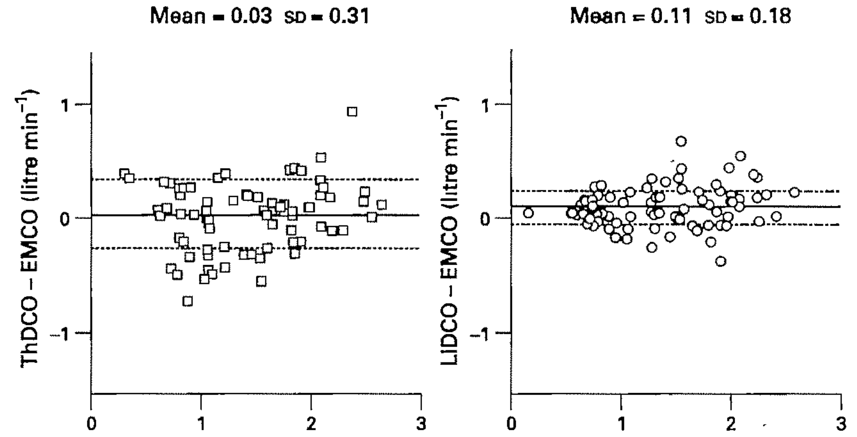

Figure 2 Difference between ThDCO and EMCO plotted against mean (left) and difference between LiDCO and EMCO plotted against mean (right). The thick line shows the mean; broken lines indicate ±1 SD. ThDCO=Thermodilution cardiac output measurement; LiDCO=lithium dilution cardiac output measurement; EMCO=cardiac output measured by electromagnetic flowmetry.

coefficient of the linear regression line between LiDCO and EMCO (0.95) was higher than that between ThDCO and EMCO (0.87).

The bias and precision values of ThDCO and LiDCO in predicting EMCO in each haemodynamic state are given in table 1. The bias values of LiDCO were greater than those of ThDCO, except in the hyperdynamic state, and the precision values of LiDCO were less than those of ThDCO in each state. However, there was no significant difference in bias and precision values between the two methods, except the bias value at baseline 1 and the precision value in the hyperdynamic state. Taking all haemodynamic states together, the precision value of LiDCO (0.04) was significantly less than that of ThDCO (0.09), and the bias value of LiDCO (0.11) was significantly greater than that of ThDCO (0.03) (table 1).

The difference (ThDCO−EMCO) compared with (ThDCO+EMCO)/2, and the difference (LiDCO−EMCO) compared with (LiDCO+EMCO)/2 are shown in figure 2. The SD of the differences (LiDCO−EMCO) (0.18) was less than that of the difference (ThDCO−EMCO) (0.31).

Discussion

The reliability of LiDCO compared with ThDCO was assessed under general anaesthesia by comparing both with EMCO at baseline and during hyperdynamic and hypodynamic states. As we did not measure coronary blood flow, which constitutes approximately 5% of left ventricular output under resting conditions and increases by approximately 15% under hypoxia,[19] ThDCO and LiDCO should exceed the values of EMCO. The bias values of LiDCO and those of ThDCO showed positive values except for ThDCO at baseline 1 (table 1). The bias values of LiDCO were greater than those of ThDCO, except in the hyperdynamic state. The bias value of LiDCO (0.11) calculated for all haemodynamic states was significantly greater than that of ThDCO (0.03). However, bias is affected by coronary blood flow, which was not measured in our study. The precision values of LiDCO calculated for all haemodynamic states, and for each individual haemodynamic state, were significantly less (i.e. better) than those of ThDCO (table 1). These results suggest that the variation in each prediction of cardiac output by LiDCO was lower than that by ThDCO, and the LiDCO technique gave better repeatability than the ThDCO technique. Furthermore, the correlation coefficient of the relationship between LiDCO and EMCO was higher than that between ThDCO and EMCO, and the SD of the differences (LiDCO−EMCO) was less than that of the difference (ThDCO−EMCO). Our results indicate that the LiDCO technique was more reliable than the ThDCO technique.

Although the thermodilution technique with a pulmonary artery catheter has been used widely, bolus injection of ice-cold 5% glucose elicits haemodynamic changes such as slowing of heart rate,[20–22] decrease in systemic arterial pressure,[23] increase in stroke volume[24] and arrhythmias such as atrial fibrillation[25] or ventricular fibrillation.[26] Several researchers have reported severe complications resulting from pulmonary artery catheterization in addition to central venous puncture complications.[1–3] In a recent prospective cohort study, Connors and colleagues analysed 5735 critically ill adult patients receiving care in an intensive care unit.[4] They compared outcome in two groups of patients (matched for severity of illness): one group had pulmonary artery catheters inserted and the other did not. They found that pulmonary artery catheterization was associated with a 24% higher mortality, longer hospital stay and increased medical costs. As the thermodilution technique uses cold as an indicator, several factors may influence cardiac output estimation by this method.[27] Renner, Morton and Sakuma[28] conducted an animal study to determine the accuracy and reproducibility of the thermodilution technique using 5- or 10-ml room temperature or iced injectates. Their results showed that a smaller volume of room temperature injectate impaired accuracy but not reproducibility at low cardiac outputs, and that this same volume impaired reproducibility at high cardiac outputs.[28] Thermodilution measurements obtained at specific times during the respiratory cycle are known to vary by 5–20%.[29–31] Measurement errors caused by even a small cyclical variation in pulmonary blood temperature with respiration may be another factor in the variation of results in thermodilution techniques. Even if the end of expiration is used to time injection of the indicator, cardiac output is underestimated during spontaneous breathing and overestimated during continuous or intermittent positive-pressure ventilation.[32] Variations in pulmonary artery blood temperature transiently increase after cardiopulmonary bypass, and the increased thermal noise may cause significant errors in the results of thermodilution techniques.[33] Wetzel and Latson[34] reported that cardiac output was underestimated during rapid volume infusion because rapid peripheral volume infusion causes small fluctuations in pulmonary artery blood temperature. In our study, ThDCO was performed using 5 ml of ice-cold 5% glucose as the indicator and was measured during apnoea at the end of expiration to reduce baseline fluctuations in pulmonary artery blood temperature.

The lithium dilution technique causes less of a problem from loss of indicator. It cannot be lost through the injection catheter and it is not lost in its passage through the lungs, nor does it bind to plasma or tissue proteins.[13 14] Because we stopped mechanical ventilation and maintained i.v. infusion rates constant while cardiac output was measured, we kept fluctuations in baseline voltage by respiratory cycle or rapid volume infusion to a minimum. Lithium chloride injection did not elicit any haemodynamic changes. As it does not require the use of a pulmonary artery catheter, the lithium dilution technique is a less invasive method; measurements can be taken via *in situ* central venous and arterial catheters without exposing patients to any of the risks associated with the use of a pulmonary artery catheter.

Several caveats with the LiDCO system should be mentioned. (1) We administered heparin 100 u. kg^{-1} to avoid blood clotting on the sensor because clotting would cause rapid deterioration of the electrode. The sensor used in our study was a prototype disposable one, not treated with anticoagulant. We used one sensor throughout each experiment because of limited availability of the prototype sensors and because of this, administration of heparin was essential. (2) Linton, Band and Haire[12] reported that the sudden transition from room temperature saline to warm blood caused a transient drift in electrode potential. We observed this in our study; however, we had enough time for blood sample withdrawal (10–15 s) to stabilize the drift of the lithium sensors before measurement. (3) We observed a transient increase in baseline voltage for a few minutes starting just after administration of $NaHCO_3$, vecuronium or pancuronium. Although these drugs do not cause permanent unacceptable drift or deterioration of the electrode, it should be kept in mind that administration of these drugs during or immediately before the measurement time may decrease the accuracy of the lithium dilution technique. (4) The LiDCO system requires obtaining 4 ml min^{-1} of sample blood; mean blood loss for each measurement was 2.6 ml, which was less than that in the system reported by Linton, Band and Haire[12] (who withdrew 15–30 ml min^{-1}). Because the sensor is located outside the artery, sample volume loss may be unavoidable, but a decrease in sample volume may be realized in the future if a smaller sensor is designed or sample reinfusion is made possible.

The lithium dilution technique requires further examination concerning pharmacokinetics and the future safety of multiple injections of lithium chloride in clinical settings. As lithium has been administered orally as the carbonate salt (Li_2CO_3) in the treatment of many affective disorders to produce therapeutic plasma concentrations (0.5–0.8 mmol litre^{-1} obtained 12 h after the last lithium dose), the side effects and toxicity are well known. Lithium carbonate is usually prescribed in a dose of 600– 1200 mg (corresponding to 33.2–66.4 mmol of lithium ion) daily in divided doses.[35] Linton, Band and Haire,[12] who administered 0.6 mmol of lithium chloride in one measurement, reported that the peak concentration of lithium was 1.3 mmol litre^{-1} only a few seconds after administration, and they found that awake subjects experienced no sensations when given doses of lithium chloride up to 1 mmol i.v. We carried out LiDCO eight times in one experiment with the dose level at 0.1 mmol (0.67 ml of a 0.15-mol litre^{-1} solution). In our study, we did not measure the concentration time course of lithium after experiments, but the mean peak concentration of lithium appearing for a few seconds in dilution curves was 0.89 mmol litre^{-1} (maximum 1.44 mmol litre^{-1}, minimum 0.31 mmol litre^{-1}). Although the amount of lithium administered by the i.v. route in one measurement is much less than that administered by the oral route in the treatment of affective disorders, pharmacokinetics and the emergence of side effects by multiple injections over a short time should be investigated to determine safety and dose limitations.

Detection of arrhythmogenic cellular magnesium depletion in hip surgery patients

G. ZUCCALÀ, M. PAHOR, F. LATTANZIO, S. VAGNONI, F. RODOLÀ, P. DE SOLE, A. CITTADINI, A. COCCHI AND R. BERNABEI

Summary

The use of high-dose magnesium infusions in critically ill and surgical patients is increasing. This practice is associated with considerable risk of toxicity, as no reliable criteria are currently available to detect significant intracellular magnesium depletion. We have evaluated, before and after surgery, 33 elderly patients with hip fracture, by 24-h Holter ECG monitoring, Doppler echocardiography and serum chemistry; lymphocyte magnesium was measured using atomic absorption spectrophotometry. The severity of ventricular arrhythmias increased, and serum and mononuclear magnesium concentrations decreased significantly after surgery. Decreases in either serum magnesium concentrations >0.125 mmol litre^{-1} or cellular magnesium >6 nmol mg^{-1}, but not serum or lymphocyte absolute magnesium concentrations, were associated with postoperative development of repetitive arrhythmias. Variations in serum magnesium concentrations correlated with intracellular decreases, and yielded good accuracy in predicting the postoperative worsening of arrhythmias. Thus perioperative differences in serum magnesium concentrations reflected intracellular variations and allowed us to identify patients with clinically relevant cellular magnesium depletion. (*Br. J. Anaesth.* 1997; **79**: 776–781).

Key words
Ions, magnesium. Complications, magnesium depletion. Heart, arrhythmia. Measurement techniques, spectrophotometry. Surgery, orthopaedic.

In recent years magnesium depletion has proved a common condition in patients with acute myocardial infarction[1–3] in the intensive care unit and after major surgery.[4–12] Magnesium deficiency has been associated with increased occurrence of cardiac arrhythmias, both after operation[8–12] and in acute myocardial infarction.[13–15] In addition, hypomagnesaemia has been associated with increased mortality both in postoperative and intensive care patients.[16 17] Thus routine magnesium therapy is expected to be used with increasing frequency in intensive care settings and operating rooms,[18 19] also because of increasing evidence of its beneficial effects on postoperative cardiac function and rhythm, muscle strength, vascular tone and central nervous system metabolism.[10 20–22]

In patients with myocardial infarction, systematic administration of magnesium has been shown to decrease the incidence of ventricular fibrillation, but with detrimental effects on survival.[23 24] This outcome was associated with an excess incidence of cardiogenic shock and heart failure;[25] indeed, excessive intracellular magnesium concentrations can depress cardiac function.[26 27] It has been acknowledged that safe and effective magnesium treatment as a clinical routine is still hindered by the lack of correlation between serum and tissue magnesium concentrations; the value of other clinically available methods to detect magnesium deficiency, such as measurement of ultrafilterable magnesium or 24-h urinary excretion, is at best uncertain.[6 9–11 28 29]

Atomic absorption spectrophotometry is the most reliable method currently available to measure intracellular magnesium content.[30] Mononuclear blood cell magnesium concentrations, as determined by this method, correlate well with myocardial concentrations in patients undergoing heart surgery.[11] Nevertheless, this method is too expensive and difficult to implement to be used routinely.[10 11 31]

We have studied a series of older patients undergoing hip surgery to identify any variables that may be useful in clinical practice to detect "relevant" intracellular magnesium depletion, that is independently associated with postoperative development of repetitive ventricular arrhythmias.

Patients and methods

We studied 52 older patients (mean age 80 (range

61–100) yr) with proximal femur fracture, consecutively admitted to the orthopaedics ward of the University Hospital A. Gemelli from January 1 to June 30, 1994. Patients with pacemaker rhythm (three cases), chronic atrial fibrillation (four cases), pulmonary embolism (three cases), unreliable mononuclear cell magnesium assay (six cases) or those receiving antiarrhythmic drug therapy (three cases) were excluded. Thus the study included 33 subjects (two males, 31 females; mean age 82 (range 62–100) yr) whose characteristics are shown in table 1. Twelve patients suffered from coronary disease, 12 from hypertensive heart disease and four from both conditions; however, no patient showed signs or symptoms, or reported history of heart failure.

SURGERY

Femoral fractures were treated by compression screw-plate in 18 patients and by cemented total hip arthroplasty in 15. All patients received oral diazepam and i.m. atropine as premedication. General anaesthesia comprised induction with thiopentone 3–4 mg kg^{-1} and vecuronium 0.08 mg kg^{-1}, and maintenance with isoflurane and nitrous oxide in oxygen, with fentanyl 4 mg kg^{-1} h^{-1} i.v. During operation, the ECG, non-invasive arterial pressure, pulse oximetry and end-tidal analysis of expired gas were monitored throughout anaesthesia. Postoperative pain was controlled by ketorolac i.v. From the beginning of surgery to the postoperative period, Holter monitoring and blood sample collection, patients received a mean of 5742±772 ml of i.v. fluids, with sodium 598 mmol litre^{-1}, potassium 37.5 mmol litre^{-1}, calcium 3 mmol litre^{-1} and magnesium 6.25 mmol litre^{-1}.

DATA COLLECTION

All patients were evaluated by history, physical examination, blood chemistry, chest x-ray, electrocardiography, Doppler echocardiography and urinalysis. In addition, 24-h Holter monitoring was performed (using a full-disclosure Oxford Medilog RF/12 DR system) 48 h before, and from 18 to 20 h after surgery. Two leads (CM1 and CM5) were recorded and analysed independently by two physicians who were blinded to all clinical data. Ventricular arrhythmias were classified according to Lown and co-workers: class 1 (less than 30 ectopic beats per hour), 2 (30+ ectopic beats per hour), 3 (multifocal beats), 4A (couplets) and 4B (ventricular tachycardia).[32] The fifth class (R-on-T phenomenon) was not recorded in our patients. Doppler echocardiograms were obtained at the beginning of each Holter monitoring; all investigations were performed by a phased-array system, equipped with a 3.5-MHz probe (2.5 MHz during pulsed Doppler sampling). The left ventricular mass was calculated by a validated method.[33]

Mononuclear blood cells were obtained for measurement of intracellular magnesium content within the first hour of each Holter monitoring from duplicate 10-ml samples of heparinized blood, obtained from the antecubital fossa after removing the tourniquet. Lymphocytes were obtained from whole blood by separation on a discontinuous density gradient (Lymphoprep, Nycomed, Oslo).[34] The mononuclear cell layer was washed in isotonic saline and the cell pellet lysed by resuspending in 1.2 ml of distilled water. Immediately after lysis, 0.5-ml aliquots were diluted 1:1 with sodium phosphate buffer 20 mmol litre^{-1}, pH 7.4, for protein analysis, or nitric acid 0.2 mol litre^{-1} for magnesium assay, and stored at −20°C. Protein analysis was carried out using the Bradford method, with 1 mg ml^{-1} of albumin solution as standard.[35] Cell magnesium was measured by atomic absorption spectroscopy.

As it is difficult to measure accurately lymphocyte magnesium concentrations,[31] we obtained duplicate specimens for each patient from a single venepuncture, and these were processed independently. Magnesium mononuclear cell values were used in the study only if the results in the two specimens differed by less than 15% of the mean value of the two specimens.[31] This standard was not met in six (15%) of the duplicate specimens.

STATISTICAL ANALYSIS

Data for continuous variables are presented as mean (SEM). Statistical analysis was performed using EpiInfo III and SPSS for Windows 6.0.1 statistical softwares; differences were considered significant at $P<0.05$. The variations in Lown classification induced by surgery were evaluated by the Wilcoxon matched pairs rank test. Comparisons between pre- and postoperative variables were performed by the two-tailed paired Student's t test. Analysis of variance for normally distributed variables in relation to both postoperative Lown classification and perioperative variations in Lown classes of arrhythmias was performed by ANOVA comparisons; otherwise, non-parametric tests, such as Kruskal–Wallis H, were adopted.

Because no established cut-offs are available to diagnose magnesium depletion, linear discriminant analysis was used to test in separate models the association of perioperative differences in serum and cellular magnesium concentrations with postoperative worsening of ventricular arrhythmias.[36]

Logistic regression analysis with forward stepwise selection of covariates, based on conditional variable estimates, was used to assess the association of cellular and serum magnesium variations with postoperative worsening of Lown classification. As cellular and serum magnesium differences were collinear measures, these variables were analysed in separate models. In the regression models patients with serum and cellular magnesium decreases >0.125 mmol litre^{-1} and >6 nmol mg^{-1}, respectively, were compared with those with lower degrees of magnesium depletion. According to linear discriminant analysis, these thresholds yielded the best accuracy in predicting worsening of ventricular arrhythmias.[36] The following covariates were also examined as potential confounders in the regression models: age; sex; pre- and postoperative serum creatinine, sodium, calcium and potassium concentrations, and their perioperative differences; type and duration of surgery; preoperative Lown classification; amount of fluids and electrolytes administered; occurrence of intraoperative hypotension; occurrence of severe blood loss with necessity of transfusion; presence of cardiovascular disorders; and preoperative cellular and serum magnesium concentrations.

Finally, the Pearson's correlation coefficient for perioperative variations in serum and cellular magnesium was calculated. Also, stepwise linear regression analysis was used to build an equation that predicted the variations in intracellular magnesium from a series of clinically available variables. The covariates entered in this model included: age; sex; presence of cardiovascular disorders; type and duration of surgery; amount of fluids and electrolytes administered; occurrence of intraoperative hypotension; occurrence of severe blood loss with subsequent transfusion; preoperative cellular magnesium concentrations; and the perioperative differences in serum concentrations of magnesium, sodium, calcium, potassium and creatinine.

Results

VENTRICULAR ARRHYTHMIAS

No patient developed significant arrhythmias during surgery. The average frequency of ventricular ectopic beats did not differ between preoperative and postoperative Holter recordings (206 (76) *vs* 214 (102) beat h^{-1}, respectively; P=0.9). However, postoperative worsening of Lown classification of ventricular arrhythmias (table 2) was detected by Holter monitoring in 18 patients (55%), while the severity of arrhythmias was unchanged in 13[37] and decreased in two (6%); the perioperative difference for all patients, as evaluated by the Wilcoxon rank test, was significant (z=2.77, P=0.005). After operation, nine (27%) patients showed repetitive ventricular arrhythmias that were not detectable before surgery. Among these, two (6%) had runs of sustained ventricular tachycardia (from 12 to 30 beats); one died suddenly approximately 24 h after Holter monitoring. There were no signs of pulmonary embolism or myocardial infarction at necropsy, thus supporting the hypothesis of arrhythmic death.

Table 2 Lown classes of ventricular arrhythmias

Class	Preoperative (*n* (%))	Postoperative (*n* (%))
0	8 (25)	6 (18)
1	14 (42)	10 (30)
2	2 (6)	4 (12)
3	4 (12)	2 (6)
4a	5 (15)	9 (28)
4b		2 (6)

BLOOD CHEMISTRY

After surgery, significant reductions in serum albumin, calcium, and in both cellular and serum magnesium concentrations occurred. There were no differences in serum potassium, sodium, chloride, ureic nitrogen, creatinine or phosphate concentrations (table 1).

CORRELATES OF POSTOPERATIVE ARRHYTHMIAS

There were no significant differences in clinical or Doppler echocardiographic variables with respect to postoperative Lown classification of arrhythmias or perioperative variations.

Preoperative Lown classification (P=0.0015) and extent of intracellular magnesium loss (P=0.04) were the only variables associated with postoperative Lown classification. When postoperative worsening of Lown

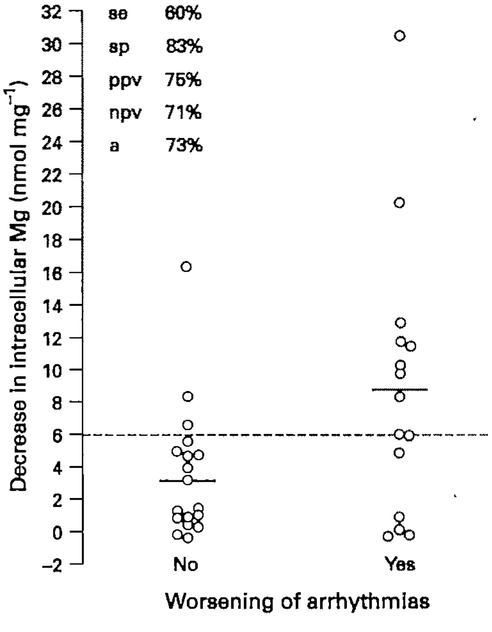

Figure 1 Individual variations in lymphocyte magnesium content according to the postoperative increase in severity of ventricular arrhythmias. The solid lines represent group means; broken line indicates the threshold value (calculated with linear discriminant analysis) above which worsening was most likely to occur. Also shown are sensitivity (se), specificity (sp), positive predictive value (ppv), negative predictive value (npv) and predictive accuracy (a) for this threshold.

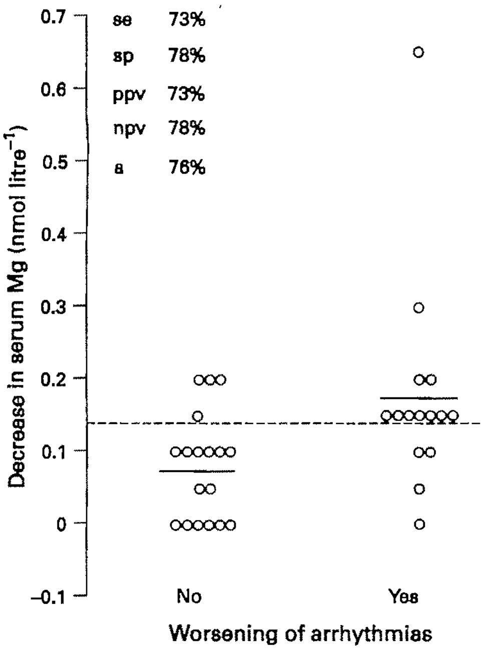

Figure 2 Individual variations in serum magnesium concentrations according to the postoperative increase in severity of ventricular arrhythmias. The solid lines represent group means; broken line indicates the threshold value (calculated with linear discriminant analysis) above which worsening was most likely to occur. Also shown are sensitivity (se), specificity (sp), positive predictive value (ppv), negative predictive value (npv) and predictive accuracy (a) for this threshold.

classification was examined, greater perioperative differences in cellular (P=0.019) and serum (P=0.013) magnesium and in serum calcium concentrations (P=0.005) were the only variables associated with postoperative changes to higher classes.

The linear discriminant analysis indicated that perioperative variations in both cellular (fig. 1) and serum (fig. 2) magnesium concentrations predicted postoperative worsening of ventricular arrhythmias. The best predictive accuracy was obtained using threshold levels of 0.125 mmol litre^{-1} and 6 nmol mg^{-1} as decreases in serum and cellular magnesium, respectively (figs 1, 2).

Perioperative differences in serum and cellular magnesium and in serum calcium concentrations were the only variables that entered the final conditional logistic regression models, and were therefore independently associated with postoperative worsening of arrhythmias. The first two rows in table 3 refer to partial models, not adjusted for difference in serum calcium. It is noteworthy that while the odds ratio for the decrease in serum magnesium was not affected substantially by adjustment for serum calcium difference (model 3), the statistical significance of cellular magnesium depletion was enhanced markedly when serum calcium variation was entered into the model (model 4).

Table 3 Conditional logistic regression results relating the perioperative differences in serum and intracellular magnesium concentrations (evaluated in separate models) to the postoperative increase in Lown classification

	Odds ratio	95% CI	P
Models not adjusted for variations in serum calcium			
Serum magnesium			
(decrease >1.25 mmol litre^{-1})	9.62	1.95–47.4	0.005
Cellular magnesium			
(decrease >6 mmol mg^{-1})	7.50	1.49–37.7	0.014
Models adjusted for variations in serum calcium			
Serum magnesium			
(decrease >1.25 mmol litre^{-1})	8.36	1.37–50.9	0.021
Cellular magnesium			
(decrease >6 mmol mg^{-1})	29.5	2.37–368.3	0.008

CORRELATES OF CELLULAR MAGNESIUM DEPLETION

While pre- and postoperative absolute serum concentrations of magnesium did not correlate with intracellular concentrations, a significant correlation was found between perioperative differences in serum and lymphocyte concentrations (r=0.62; P=0.0001). The perioperative difference in serum magnesium was the only variable that entered the final linear regression model, and was therefore independently associated with variations in intracellular magnesium.

The resulting regression equation was

$$\Delta_{\text{cell}}\ \text{Mg}=1.59+\Delta_{\text{serum}}\ \text{Mg}\times 35.26$$

where Δ_{cell} Mg=perioperative difference in lymphocyte magnesium content (expressed as nmol mg^{-1}), and Δ_{serum} Mg=difference in serum magnesium (mmol litre^{-1}).

Discussion

We have found that postoperative arrhythmogenic cellular magnesium depletion corresponded with a >10% reduction in intracellular concentrations, rather than with a simply "low" total cellular content. In addition, while absolute serum and cellular magnesium concentrations did not correlate, perioperative intracellular variations were associated with differences in serum concentrations by a simple equation, so that patients at risk of development of repetitive ventricular arrhythmias may be identified accurately by monitoring serum magnesium concentrations. Knowledge of variations in intracellular magnesium content from serum assays may be crucial for safe and effective management of high-dose magnesium therapy in patients at risk of magnesium depletion.

Our study focused on detection of postoperative arrhythmogenic cellular magnesium depletion in hip surgery; the clinical value of this study model was confirmed by the significant postoperative increase in repetitive ventricular arrhythmias (table 2). This observation is in agreement with previous observations on the arrhythmogenic role of major surgery; in some studies, magnesium depletion has been identified as the main culprit.[8–12]

In our patients, magnesium depletion was the major determinant of the postoperative increase in severity of arrhythmias (table 3). The independent association of magnesium depletion with postoperative ventricular ectopic activity was significant, even after adjustment for potential confounders, such as potassium and calcium serum concentrations, or their perioperative variations.

The results of this study suggest that postoperative magnesium depletion should be considered in terms of perioperative variations in intracellular concentrations, rather than as "low" total cellular content. This finding is in agreement with experimental studies on magnesium mobilization from cardiac myocytes. These studies showed that most intracellular magnesium is complexed (i.e. inactive) and that only rapid outward magnesium fluxes (ranging from 10 to 15% of total content) yield significant effects on cellular metabolism and electrophysiology through redistribution of subcellular magnesium fractions.[38] Noticeably, the threshold level for the decrease in intracellular magnesium that best predicted postoperative worsening of ventricular arrhythmias in our patients corresponded with approximately 10% of the mean preoperative cellular content (table 1). Other studies also found no relation between total serum or cellular magnesium content and arrhythmias.[29 31 37 39]

Even though simultaneous serum and monocyte magnesium concentrations did not correlate, perioperative differences in serum concentrations reflect intracellular variations, and allow simple prediction of postoperative worsening of ventricular arrhythmias with reasonable accuracy (fig. 2). Indeed, a correlation between changes in serum and myocardial magnesium has been reported in a longitudinal study.[37]

According to the final regression equation, a decrease in serum magnesium concentration of 0.125 mmol litre^{-1} would correspond to a reduction in intracellular concentrations of 5.99 nmol mg^{-1}. These values correspond to threshold levels that in separate models of discriminant analysis best predicted postoperative worsening of arrhythmias (figs 1, 2).

It is unclear why the association between cellular magnesium depletion and worsening arrhythmias was increased after adjusting for serum calcium variations, compared with the unadjusted analysis (table 3). The interrelations between magnesium and calcium variations are complex and not completely understood. Low serum calcium concentrations may enhance cellular magnesium depletion and, conversely, hypocalcaemia can result from magnesium depletion.[10 37 40 41]

In this study, 20 (61%) patients were hypomagnesaemic after surgery; this is similar to the reported prevalence of hypomagnesaemia (69%) after cardiac surgery.[42] The loss of magnesium after surgery has been attributed to intraoperative administration of magnesium-free fluids, and to increased serum cathecholamine concentrations.[7 10 12 29] Similarly, magnesium depletion in patients with acute myocardial infarction has been associated with increased serum noradrenaline concentrations.[13 15] Indeed, massive magnesium release from myocytes has been demonstrated after stimulation with noradrenaline; such an efflux is independent of extracellular magnesium concentrations.[38] In surgical settings, increased noradrenaline serum concentrations have been observed for several days after interventions.[43 44] These observations are in keeping with the reported persistence of magnesium loss during the early postoperative period,[45] and the transient efficacy of single magnesium infusions.[10] Therefore, protracted, high-dose magnesium supplementation has been recommended in patients with acute myocardial infarction or in those undergoing major surgery.[10 18 19 46] However, in large studies in patients with acute myocardial infarction (such as the LIMIT-2 and ISIS-4 studies) treatment with high-dose magnesium has been found either to decrease or increase mortality.[23 46] Sustained monitoring of serum concentrations of magnesium in these patients might allow us to identify subjects with significant intracellular depletion in whom magnesium administration would yield the best risk–benefit ratio.

Partly exhausted soda lime or soda lime with water added, inhibits the increase in compound A concentration in the circle system during low-flow sevoflurane anaesthesia

G. MORIWAKI, H. BITO AND K. IKEDA

Summary

We performed low-flow sevoflurane anaesthesia at a flow rate of 1 litre min^{-1} in three groups ($n=8$ each) using 600 g of fresh soda lime (control group), 600 g of soda lime with 60 ml of water added (water group) or 600 g of soda lime saturated with carbon dioxide, that is partly exhausted soda lime (carbon dioxide group). Degradation products in the system were measured hourly. Inspired and end-tidal carbon dioxide and sevoflurane concentrations, carbon dioxide and temperature of the soda lime were monitored. $CF_2=C(CF_3)\text{-O-}CH_2F$ (compound A) was the only sevoflurane degradation product detected. The mean maximum concentration of compound A was significantly higher in the control group (mean 16.0 (SD 5.0) ppm) than in the water (1.4 (1.0) ppm) or carbon dioxide (4.0 (1.8) ppm) group, and the maximum temperature of the soda lime was significantly lower in the carbon dioxide group (30.7 (3.5)°C) than in the control (43.4 (1.8)°C) or water (40.8 (1.8)°C) group ($P<0.05$). The use of partly exhausted soda lime or soda lime with water added reduced compound A concentrations in the system during low-flow sevoflurane anaesthesia. (*Br. J. Anaesth.* 1997; **79**: 782–786).

Key words
Anaesthetics volatile, sevoflurane. Equipment, breathing systems. Carbon dioxide, absorption.

Sevoflurane is known to react with carbon dioxide absorbents, resulting in generation of five degradation products.[1 2] Among these degradation products, $CF_2=C(CF_3)\text{-O-}CH_2F$ (compound A) has been reported to be nephrotoxic in rats,[2–5] suggesting that it may be desirable in clinical practice to minimize its production. It has been reported that compound A concentrations in the circle system tend to decrease over time during closed or low-flow sevoflurane anaesthesia[6 7] and that fresh soda lime tends to produce higher concentrations of compound A than partly exhausted soda lime.[8] Therefore, we felt that the use of partly exhausted soda lime (prepared by exposing soda lime to carbon dioxide) rather than fresh soda lime might inhibit the production of degradation products during low-flow sevoflurane anaesthesia. It has also been reported that decreasing the water content of soda lime increases the production of sevoflurane degradation products *in vitro*.[9 10] However, there have been no clinical studies on the effects of soda lime with water added on the generation of degradation products during sevoflurane anaesthesia. In this study, we performed low-flow sevoflurane anaesthesia using fresh soda lime, soda lime with water added and soda lime saturated with carbon dioxide to investigate the effects of these differences in soda lime on the concentration of degradation products in the system.

Patients and methods

This study was approved by the Institutional Committee on Human Research and informed consent was obtained from all patients.

We studied 24 patients, ASA I or II, undergoing tympanoplasty. Patients were allocated randomly to one of three groups ($n=8$ each) to undergo low-flow sevoflurane anaesthesia with three different carbon dioxide absorbents. In the control group, anaesthesia was performed using 600 g of fresh soda lime (Sodasorb II, WR Grace, Lexington, MA, USA). In the water group, anaesthesia was performed using 600 g of fresh soda lime to which 60 ml of distilled water at 25°C was added immediately before use. In the carbon dioxide group, 600 g of partly exhausted soda lime was used. The partly exhausted soda lime was prepared by placing 600 g of fresh soda lime in an anaesthesia system equipped with a 1-litre test lung, with the oxygen flow rate set to 1 litre min^{-1} and a carbon dioxide flow rate of 200 ml min^{-1}, ventilating the test lung with a tidal volume of 500 ml at a rate of 12 cycles min^{-1} for 6 h, and then removing the soda lime and leaving it at room temperature for 6 h.

GOROKU MORIWAKI, MD, HIROMICHI BITO, MD, KAZUYUKI IKEDA, MD, FRCA, Department of Anaesthesiology and Intensive Care, Hamamatsu University School of Medicine, 3600 Handa-cho Hamamatsu 431-31, Japan. Accepted for publication: July 30, 1997.

Patients were premedicated with hydroxyzine 50 mg and atropine 0.5 mg i.m., 30 min before entering the operating room. Anaesthesia was induced with thiopentone 4–5 mg kg^{-1} and vecuronium 0.12–0.15 mg kg^{-1}. After intubation of the trachea and connection to the anaesthesia system, the fresh gas flow rate was set to nitrous oxide 0.6 litre min^{-1} and oxygen 0.4 litre min^{-1}. The lungs were ventilated mechanically with a tidal volume of 10 ml kg^{-1}, and ventilation rate was adjusted to maintain an end-tidal carbon dioxide partial pressure of 4.0–5.3 kPa. The concentration of sevoflurane was adjusted to maintain systolic arterial pressure within ±20% of baseline. The anaesthesia machine used was a Modulas II Anesthesia System (Ohmeda, Madison, WI, USA). The operating room was maintained at a temperature of 25 °C and 50% relative humidity.

The following variables were measured after the start of mechanical ventilation. The temperature of the soda lime was recorded every 15 min using a temperature probe (temperature probe model 9182, Hioki Electric Co., Nagano, Japan) inserted into the centre of the canister. Inspired and end-tidal carbon dioxide concentrations and inspired and end-tidal sevoflurane concentrations were monitored by mass spectrometry (Medical Gas Analyzer 1100, Perkin Elmer, Pomona, CA, USA). Minute carbon dioxide production by the patient was calculated based on minute expired volume and mean expired carbon dioxide concentration. Minute expired volume and mean expired carbon dioxide concentrations were measured using a linearized electric Wright respirometer (BOC Medishield, Essex, UK) and a bypassed mini-mixing chamber for mass spectrometry, respectively. Gas samples for measurement of degradation products were obtained from the inspiratory limb of the anaesthesia system every hour until 3 h after termination of anaesthesia..

Sample gas for measurement of degradation products was collected from the inspiratory limb of the anaesthesia system using a gas-tight syringe (20 ml). Concentrations of degradation products were measured using a gas chromatograph (model GC-9A, Shimadzu, Kyoto, Japan) equipped with a gas sampler (model MGS-5, Shimadzu, Kyoto, Japan). The sample volume was 1 ml. For gas chromatography, the column temperature was 100 °C and the injection inlet temperature was 140 °C; nitrogen was used as the carrier gas at a flow rate of 50 ml min^{-1}. The detector was a hydrogen flame ionization detector (FID). The column was a glass column, 5 m in length, 3 mm internal diameter, filled with 20% DOP Chromosorb WAW (Technolab S.C. Corp., Osaka, Japan), 80/100 mesh. The gas chromatograph was calibrated against a standard calibration gas prepared from stock solutions of compound A.

In order to determine the water content of the soda lime, samples of fresh soda lime were treated in the same way as in each group and the water content was then measured. In addition, three 600-g samples of fresh soda lime and three 600-g samples of fresh soda lime with water added were processed in the same way as the soda lime used in the carbon dioxide group, and the time at which carbon dioxide was no longer absorbed in the inspiratory limb of the circle system was measured.

All values are expressed as mean (SD). The concentration of compound A, temperature of the soda lime, end-tidal sevoflurane concentration and carbon dioxide production were compared by one-way analysis of variance (ANOVA) followed by Bonferroni/Dunn. $P<0.05$ was considered statistically significant.

Results

There were no significant differences in age, height or body weight between the three groups (table 1). The only degradation product of sevoflurane detected was $CF_2=C(CF_3)$-O-CH_2F (compound A). The maximum concentration of compound A was higher in the control group than in the water or carbon dioxide group ($P<0.05$) (table 2). There were no significant differences between the groups in end-tidal sevoflurane concentration at the time of measurement of the individual maximum concentration of compound A (table 2).

The individual maximum temperature of the soda lime was significantly lower in the carbon dioxide group than in the two other groups ($P<0.05$) (table 2). The concentration of compound A in the circle system at each measurement point decreased 60 min after the start of measurement in the following order:

Table 1 Patient characteristics (mean (SD) or range)

	Age (yr)	Height (cm)	Body weight (kg)
Control group	59.3 (36–76)	154.9 (8.5)	53.6 (8.3)
Carbon dioxide group	54.6 (32–68)	155.9 (4 2)	56.0 (8.1)
Water group	59.0 (43–72)	157.4 (7.6)	49.8 (6.5)

Table 2 Maximum compound A concentration, corresponding end-tidal sevoflurane concentration and maximum temperature of soda lime (mean (SD)). Corresponding end-tidal sevoflurane concentration = end-tidal sevoflurane concentration when individual maximum compound A were observed. *$P<0.05$ compared with carbon dioxide group and water group; †$P<0.05$ compared with control group and water group

	Maximum compound A concn (ppm)	Corresponding end-tidal sevoflurane concn (%)	Maximum temperature of soda lime (°C)
Control group	16.0 (5.0)*	1.9 (0.4)	43.4 (1.8)
Carbon dioxide group	4.0 (1.8)	1.7 (0.3)	37 0 (3.5)†
Water group	1.4 (1.0)	1.8 (0.4)	40 8 (1.8)

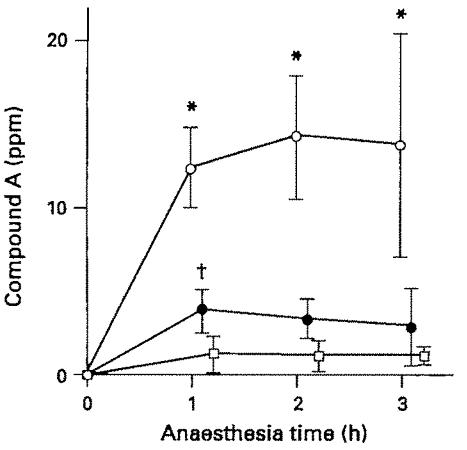

Figure 1 Concentrations of compound A in the anaesthesia system with fresh soda lime (O), partly exhausted soda lime (●) and soda lime with water added (☐) (mean, SD). $^{*}P<0.05$ compared with partly exhausted soda lime and soda lime with water added; $^{\dagger}P<0.05$ compared with soda lime with water added.

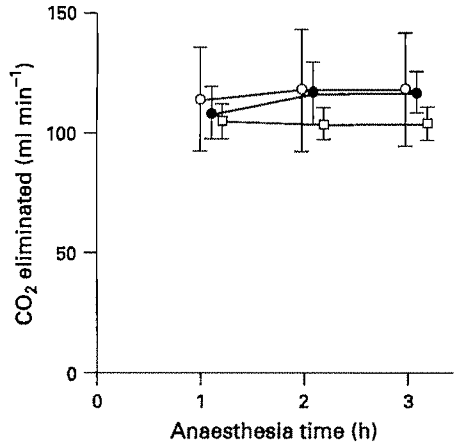

Figure 2 Hourly mean carbon dioxide eliminated by the patient with fresh soda lime (O), partly exhausted soda lime (●) and soda lime with water added (☐) (mean, SD).

control group >carbon dioxide group >water group (i.e. the lowest concentration of compound A was seen in the water group). The differences between the three groups were significant. However, significant differences were observed only between the control and water groups and between the control and carbon dioxide groups at 120 and 180 min ($P<0.05$) (fig. 1).

There were no differences in mean carbon dioxide production per hour between the groups (fig. 2). End-tidal sevoflurane concentrations also did not differ significantly between the groups (fig. 3). In the carbon dioxide group, rebreathing was observed in three of the eight patients, but end-tidal carbon dioxide partial pressure was maintained at 4.0–5.3 kPa until the end of the experiment in these three patients. The water content in the soda lime was 18% in the control group, 8% in the carbon dioxide group and 27% in the water group. Under the conditions used in our study, the soda lime with water added lost its ability to absorb carbon dioxide approximately 1–2 h sooner than fresh soda lime (fig. 4).

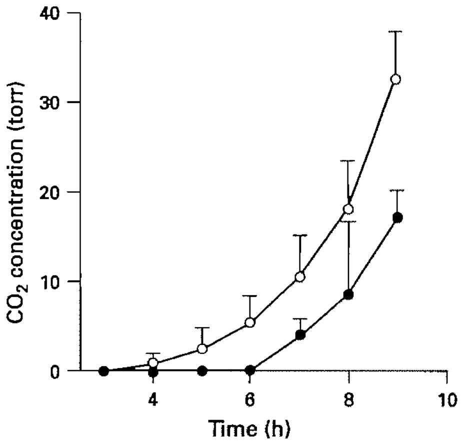

Figure 4 Concentrations of carbon dioxide in the inspiratory limb of the anaesthesia system with fresh soda lime (●) and soda lime with water added (O) (mean, SD).

Discussion

The results of our study indicated that concentrations of compound A in the circle system were reduced significantly during low-flow sevoflurane anaesthesia when partly exhausted soda lime or soda lime with water added, rather than fresh soda lime, was used as the carbon dioxide absorbent. It is unclear if low-flow sevoflurane anaesthesia can lead to renal injury in humans. Some reports indicated that low-flow sevoflurane anaesthesia had no effect on renal function in patients,[11 12] however, at least one study suggested that low-flow sevoflurane anaesthesia could cause renal injury and that compound A in particular might contribute to this injury.[13] It was reported that compound A produced renal injury dose-dependently in rats.[3–5] Therefore, a reduction in compound A concentration in the circle system during low-flow anaesthesia is considered important for ensuring safety.

There are three possible explanations for the successful reduction of compound A in our circle system. The first is that the differences in compound A concentration resulted from differences in the temperature of soda lime. It was found in *in vitro* studies that increasing the temperature of the soda lime increased the degradation of sevoflurane and the production of compound A,[9 14] suggesting that reducing the temperature of soda lime should inhibit the production of compound A in the anaesthesia system.[15] In our study, the mean maximum temperature of the soda lime was 43.4 °C in the control group, and temperatures were 6.4 °C lower in the carbon dioxide group and 2.6 °C lower in the water group, with no significant difference between the water and control groups. Strum, Johnson and Eger[14] showed that the rate of degradation of sevoflurane was related linearly to temperature. However, in our study, the decrease in compound A concentration in the circle system was greater than the decrease in temperature of the soda lime.

The second possible reason for our results is that the differences in compound A concentration resulted from differences in the components of the soda lime. In exhausted soda lime, the components of soda lime (i.e. calcium hydroxide, potassium hydroxide and sodium hydroxide) are reduced by reactivity with carbon dioxide. It has been suggested that the hydroxyl groups present on the components of soda lime might be related to the production of the degradation products of sevoflurane.[16] Therefore, the reactivity of exhausted soda lime with sevoflurane might be reduced because of a decrease in the number of hydroxyl groups, resulting in a decrease in compound A concentration in the circle system.

The third possible reason for our results is that the differences in compound A concentration resulted from differences in water content. The *in vitro* study showed that dry soda lime produces higher levels of sevoflurane degradation products than fresh soda lime,[10] whereas the half-life of sevoflurane in Baralyme increases with increases in added water.[17] Strum and Eger[10] reported that the water content of soda lime decreased from 15% with fresh to 4–8.5 % during routine clinical use. The water content measured in our sample of fresh or partly exhausted soda lime was similar to these values. Thus it can be said that compared with fresh soda lime, partly exhausted soda lime is drier and soda lime with water added is wetter. Considering water content by itself, our results suggested that water tended to increase the production of degradation products in the carbon dioxide group, while it tended to reduce such production in the water group. In our study, the production of compound A at 60 min after the start of measurement was greater in the carbon dioxide group than in the water group, despite the lower maximum temperature of soda lime and differences in the components of soda lime. Although this difference was not statistically significant, the same trend was noted at later times. This may have been a result of differences in the water content of the soda lime in each group.

Considering other factors that are thought to affect the generation of degradation products of sevoflurane, fresh gas flow rate and type of carbon dioxide absorbent (soda lime) were the same in the three groups, and carbon dioxide production by the patient and concentration of sevoflurane in the circle system did not differ significantly between the groups. Thus we concluded that these three contributing factors were interdependent, leading to a decrease in compound A concentration in the circle system in the carbon dioxide group and in the water group. The relative importance of these factors should be assessed in future studies.

Partly exhausted soda lime has a lower carbon dioxide absorbing capacity than fresh soda lime, and therefore the long-term use of exhausted soda lime in anaesthesia may be questioned. In our study, rebreathing was observed in three patients in the carbon dioxide group. This raises the question of the carbon dioxide absorption capacity of soda lime with water added. Our findings indicate that soda lime with water added loses its ability to absorb carbon dioxide only 1–2 h sooner than fresh soda lime, suggesting that it can be used for a period of time.

The results of our study indicated that the use of partly exhausted soda lime or soda lime with water added reduced compound A concentrations in the circle system during low-flow sevoflurane anaesthesia. In particular, soda lime with water added, although its ability to absorb carbon dioxide is decreased, reduced compound A concentrations in the circle system by a factor of 4 compared with fresh soda lime, suggesting that it may prove useful in clinical practice.

REVIEW ARTICLE

Opioid systems and the newborn

D. F. MARSH, D. J. HATCH AND M. FITZGERALD

The neonatal central nervous system (CNS) is both structurally and functionally immature, and significant changes in opioid analgesic mechanisms occur both before and after birth. Recent research has shown that neonatal pain pathways are different from those of older children and adults, and it is thought that analgesic mechanisms are therefore also likely to differ significantly.[18] However, our understanding of the neurobiology and development of pain pathways is still limited.

In this review we discuss our current understanding of the developmental neurobiology of opioids and the action of opioids in the human neonate. We review briefly background studies of opioid actions in adults and then focus on actions in neonates. The discussion includes both basic laboratory studies and clinical pharmacology, issues which are usually considered separately in the literature. However, if we are to advance our knowledge and improve our management of neonatal pain it is important that they are discussed in relation to one another.

(*Br. J. Anaesth.* 1997; **79**: 787–795)

Key words
Analgesics opioid. Neonates. Model, rat.

Background

While Stertürner isolated morphine, the active ingredient of opium, in 1806, naming it after Morpheus, the God of Dreams, it was not until 1973 that opioid receptors were first described,[58 69 77] shortly before the identification of endogenous opioid peptides.[33] Despite its side effects, morphine is still used widely in the treatment of acute and chronic pain and our knowledge of opioid systems in adults has been the subject of several detailed recent reviews.[15 37 56] Current thinking on adult opioid mechanisms is therefore only briefly summarized.

Opioids act by binding with high affinity membrane receptors which comprise three major groups (mu, delta and kappa receptors) and each receptor can produce different effects. Further division into subtypes remains controversial although there is now evidence of differential effects of delta receptors in mice.[36] We still have little knowledge of the specific function of each receptor, but the recent isolation and cloning of all three will significantly advance research into their roles,[65 78] hopefully assisting the search for clinically useful opioids with highly specific functions and minimal side effects. The endogenous ligands for the opioid receptors are the opioid peptides which can be classified into three groups: enkephalins, endorphins and dynorphins. These endogenous opioids have some agonist activity at all three receptors but each receptor possesses distinct ligand selectivity.[41]

Opioid effects are mediated by several mechanisms in all areas of the CNS, with the predominant effect of decreasing neuronal firing. By stimulation of opioid receptors situated presynaptically on the terminals of neurones, opioids reduce the release of excitatory neurotransmitters involved in pain pathways.[32] Stimulation of postsynaptic receptors inhibits neurotransmission by producing hyperpolarization thus reducing evoked activity.[47] A third possible mechanism involves inhibition of one neurone which lifts inhibition on the second, allowing it to become active in its own inhibitory capacity.[15]

The spinal cord is a very important site of action of opioids where they act to modulate pain pathways. This is evident clinically in the profound analgesia produced by administration of opioids in the extradural and subarachnoid spaces. Afferent nociceptor Aδ and C fibres synapse in laminae 1 and 2 (the substantia gelatinosa) of the dorsal horn[8] and it is here that the majority of spinal cord opioid receptors are located, although a smaller percentage are found in the deeper layers of the dorsal horn.[15] In the rat, mu receptors predominate in the spinal cord, with delta and kappa receptors comprising less than one-third of the total. More than 50% of these opioid receptors are located presynaptically.[7]

The recent proliferation of research into adult pain mechanisms has demonstrated that pain transmission in the spinal cord is not through a simple circuit, but rather the arrival of noxious stimuli from the periphery via primary afferent fibres initiates a cascade of events in the dorsal horn and the complexity of these reactions allows enhancement or modulation of the pain signal.

FITZGERALD, BA, PHD, Department of Anatomy and Developmental Biology, University College London, Gower Street, London WCIE 6BT.

Neurotransmitters are released from afferent fibres, interneurones, projection and descending neurones and there is considerable interaction between these fibres. The effects of excitatory amino acids, such as glutamate in particular, have sparked considerable recent interest. Glutamate is abundant in the spinal cord and is released from both myelinated and unmyelinated fibres. Its effects are mediated by NMDA (*N*-methyl-D-aspartate) receptors in addition to non-NMDA receptors, and the former have been shown to play an important role in persistent pain states such as hyperalgesia and allodynia.[84] The NMDA receptor requires repeated or sustained stimulation by C fibres for its activation, and release of glutamate from these fibres stimulates the receptor and initiates a series of intracellular events, resulting in the phosphorylation of intracellular proteins and the opening of an ion channel normally blocked by magnesium. The resultant increase in intracellular calcium allows a greatly augmented response of the receptor to glutamate; this is essentially an elaborate positive feedback mechanism. The activated NMDA receptor leads to many forms of central hyperalgesia.[14] There is now growing evidence that NMDA receptors are involved in the mechanism of opioid tolerance.[51] Mu receptor stimulation by exogenous opioids seems to lead to the same intracellular events which result in "wind-up" of the NMDA receptor and these same mechanisms may also uncouple G-proteins from the mu receptor. This in turn results both in a decreased response of the mu receptor to opioids and activation of the NMDA receptor.[5 51] It is now becoming apparent that opioid receptors do not function in isolation but rely in part on other receptors such as NMDA to elicit their effects.

Supraspinal opioid systems contribute to analgesia by several mechanisms, including decreasing nociceptive input to the brain by altering descending and ascending control systems thereby reducing central perception of pain. Intraventricular injection of opioids in humans is clinically effective in systemically inactive doses, providing evidence for the role of supraspinal sites in the production of analgesia.[44] Intracerebral microinjection of opioid agonists in several species has allowed localization of supraspinal receptors and their contribution to analgesia to be investigated.[85] In rats, opioid receptors are distributed widely throughout the CNS, most densely in the brainstem, thalamus, amygdala, hippocampus and cortex. Mu receptors are found in the majority of these areas, whereas delta receptors are more restricted, found mostly in forebrain regions with poor binding in the midbrain and brainstem. Kappa receptors are distributed widely throughout the forebrain, midbrain and brainstem, comprising only 10% of the total number of receptors in the rat brain but up to one-third in humans.[50] The periaqueductal grey matter and medulla are involved in the descending inhibitory control of dorsal horn neurones. Several supraspinal sites of receptors are found close to the origin of these descending controls, and microinjection of opioids into these areas produces analgesia by their stimulation.

Opioids also act outside the CNS and possess "local analgesic" effects. Laboratory rat studies have demonstrated the peripheral antinociceptive actions of opioid agonists in inflammatory pain models.[73] It is thought that inflammation initiates the axonal transport of opioid receptors to the periphery and increases their number on peripheral nerve terminals; inflammation disrupts the perineurium exposing neuronal opioid receptors.[72] Endogenous peptides are produced by immune cells infiltrating the inflamed tissue.[71] Although clinical evidence is inconclusive, the results of studies of intra-articular morphine for postoperative knee pain are encouraging.[12 31] The local action of a topically applied, systemically inactive opioid lacking central side effects should have major benefits.

Developmental neurobiology of opioid systems

A lack of data in humans has led to increasing reliance on basic studies of laboratory animals in the understanding of the development and function of opioid systems in the human neonate, and the rat has become the acceptable model. The sequence of events that take place in the neurological development of the rat and human CNS are similar but it is difficult to make exact comparisons. Generally speaking, the newborn rat CNS is approximately equivalent to a 24-week human fetus at birth, a full-term neonate at 7 days and a toddler at 3 weeks. Rat CNS maturation is extremely accelerated compared with the human and is mature by 3–4 weeks.[19]

ONTOGENY OF OPIOID RECEPTORS AND LIGANDS

Opioid receptors and endogenous opioid peptides appear very early in CNS development and their ontogeny is non-uniform in the neonatal rat. The majority of receptors in the adult are mu and delta, but early in the postnatal period, on postnatal day 6 (P6), mu and kappa receptors predominate.[45] At birth, opioid receptors are present in several areas, notably the neostriatum, olfactory tubercle, rostral midbrain and later in other areas such as the thalamus and hypothalamus. Delta receptors, however, have a very different ontogeny to mu and kappa receptors and are present in low densities in the brain at birth, progressing to maximum binding in the third postnatal week. A similar pattern of ontogenesis occurs in the spinal cord with the early appearance of mu and kappa receptors and delay in the development of delta receptors until the initial postnatal period.[3]

The pattern of development of mu receptors has been elegantly demonstrated in the rat by *in vitro* quantitative receptor autoradiography. Mu receptor binding sites are concentrated in the superficial laminae of the dorsal horn in the adult, but in contrast at P1, both the superficial and deeper laminae have relatively high densities. The density of mu opioid binding sites peaks at P4, then declines gradually to reach adult levels by the third postnatal week.[38] The change in distribution of mu opioid

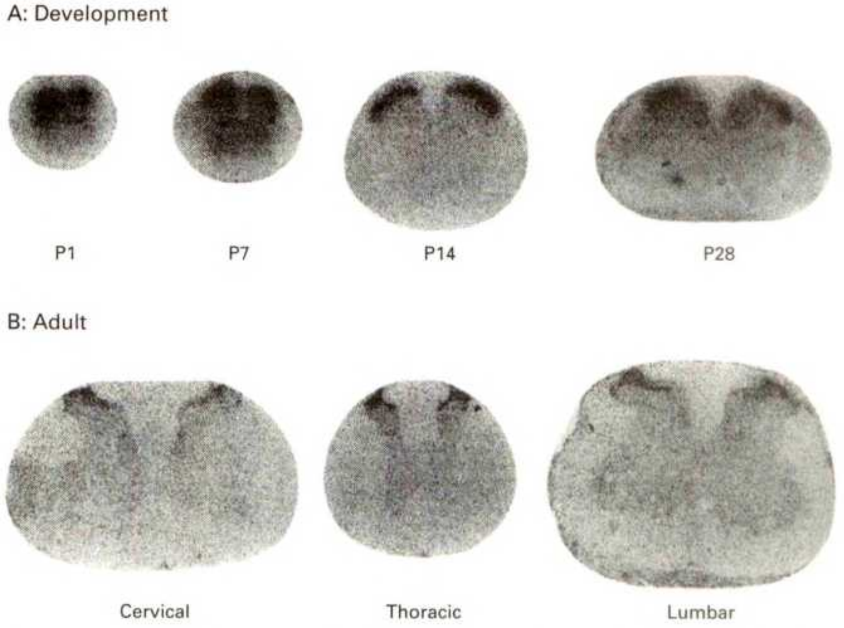

Figure 1 Photomicrographs illustrating μ receptor binding site distribution at P1, P7, P14 and P28 and at different levels of the adult rat spinal cord (modified from Kar and Quirion[38]).

binding sites in neonatal and adult rat spinal cord is shown in figure 1.

Endogenous opioids appear in the mouse brain before opioid receptors on embryonic day 11.5 (E11.5),[67] and enkephalin-like immunoreactivity is detected in rat brain at E18.[59] In human fetal spinal cord, enkephalin-like immunoreactive fibres have been detected as early as 10 weeks.[10] At E16, endorphin concentrations are much greater than enkephalin concentrations with highest concentrations in the phylogenetically newer areas of the brain such as the diencephalon and telencephalon, with a rich distribution in the limbic system. These two peptide systems appear to develop differently, with a marked increase in enkephalin concentrations during the initial perinatal period. Between P6 and P25, both endorphin and enkephalin concentrations increase to approximately adult levels.[6]

DEVELOPMENT OF SPINAL PAIN PATHWAYS RELATED TO OPIOID FUNCTION

As described, opioids play a role in pain transmission in adults by initiating descending inhibitory controls from the brainstem to the spinal cord, and by reducing the resultant activity primarily of C fibres but also of Aδ fibres in the substantia gelatinosa.

In the neonatal rat, considerable development of these pathways occurs postnatally. Although anatomically intact at birth, there is no functional descending inhibitory control until P10–12, reaching adult levels only at P22–24. This is possibly because of a delay in the development of interneurones and because of low concentrations of neurotransmitters in the postnatal period,[21] and presumably underlies the lack of brainstem stimulus-produced analgesia in newborn rats until P21.[79] C fibre and small diameter A fibres grow into the spinal cord a few days before birth, C fibres developing a considerable number of connections in the early postnatal period. However, C fibres are unable to evoke spike activity in the dorsal horn until the second postnatal week. A-fibre terminals are more widespread in the newborn terminating superficially in lamina 2 in addition to deeper laminae.[20] There is evidence that A fibre input is enhanced during this time.[34,35]

In the substantia gelatinosa of the neonatal rat, NMDA induced increases in intracellular calcium are increased markedly, gradually decreasing to adult levels. C fibre induced, NMDA mediated effects in the adult such as wind-up and central sensitization are probably more marked in the neonate, and may contribute to the establishment of C fibre connections in the cord. As in the adult, opioid receptors possibly have close links with the NMDA receptor, and their function in this respect is still unknown.[17]

ANALGESIC ACTIONS

There is ample evidence that these endogenous opioid systems contribute to functioning analgesic mechanisms in the early postnatal period, although the pattern of development of effects is difficult to establish as nociceptive physiology itself changes markedly with age, and a comparable nociceptive stimulus at different ages may be impossible to achieve. Exogenous opioids and their analgesic efficacy have been investigated in the developing rat, but difficulties in behavioural testing of neonatal animals may in part explain apparent discrepancies in the results. Preliminary data from our own laboratory have shown major difficulties with thermal testing of neonatal rats, as limb withdrawal tests seem to rely on many variables. However, despite these problems in methodology, the effect of morphine was shown to increase with age in neonatal rat pups, progressing to a 40-fold analgesic potency at P14 compared with P3 when demonstrated by a limb withdrawal test of thermal analgesia.[22] Similar results were obtained in another study of morphine analgesia in developing rats in which it was shown that morphine had no detectable effect on a tail-flick nociceptive test until P12, reaching analgesic potency comparable with adult levels at P14.[4] Comparing morphine, a potent mu agonist, and ketocyclazocine, a kappa agonist, in the developing rat revealed that morphine was more potent than ketocyclazocine in producing analgesia to limb withdrawal tests of thermal nociception, exhibiting analgesia in a dose dependant manner as early as 3 days in starting doses of 1–2 mg kg^{-1}, with peak effects at 14 days. Ketocyclazocine was more effective at producing analgesia to a mechanical stimulus (a blunt probe applied with a force of 10–15 g) in younger animals, with onset of effect at 7–10 days, this differential development in analgesic patterns confirming a non-uniform ontogeny of opioid receptors.[4] However, unlike thermal and mechanical tests of pain, the response of neonatal rats to the tonic nociceptive effects using the formalin test revealed a similar response to that seen in adults at P3. In this study it was revealed that this response was attenuated by morphine in a dose of 1–2 mg kg^{-1}, in a manner similar to adults.[55]

Early studies have warned of the susceptibility of neonates to the CNS depressant effects of opioids, but a comparison of the sedative and analgesic effects of systemic morphine and pentobarbitone in infant rats ranging in age from 1 to 20 days showed that morphine 1 mg kg^{-1} produced analgesia to an intra-plantar injection of formalin at all ages, which was different qualitatively from the sedative effects of pentobarbitone 10 mg kg^{-1}.[1] Early studies indicated that neonates were more susceptible to the convulsant effects of morphine but an investigation of the effects of high-dose morphine on EEG recordings and behavioural observations showed that although all doses of morphine used produced electrographic spikes in 1-, 3- and 6-day-old neonatal rats, behavioural convulsions were not observed suggesting morphine is less toxic than originally thought.[80]

ACTIONS OF OPIOIDS AT A CELLULAR LEVEL

There is now ample evidence to show that opioid systems play a significant part in the regulation of neuronal development in the neonate. The role of endogenous opioids in neural plasticity has been demonstrated by examining the effects of continuous receptor block on the developing neurones in the cerebral cortex, hippocampus and cerebellum in 10-day-old rats. Neonatal rats were given daily injections of the potent opioid antagonist naltrexone from P0, and after sacrifice on P10 it was demonstrated that the lengths of oblique dendrites of pyramidal cells in the cerebral cortex and basilar dendrites of the hippocampus were significantly increased compared with the control group. The dendritic lengths of spiny branches of cerebellar Purkinje cells were also increased. Endogenous opioids can therefore exert a marked influence on dendritic elaboration and spine formation.[29] In a similar study the effect of exogenous opioid block was examined at P10 and P21. Daily injections of naltrexone were given in a dose of 50 mg kg^{-1} providing complete continuous block, with 1 mg kg^{-1} producing only intermittent opioid receptor antagonism. Continuous block produced large increases in dendrite and spine elaboration at P10, but these increases were only seen in the hippocampus at P21. With intermittent block, dendrite and spine growth were often subnormal.[30] The action of met-enkephalin on the growth of astrocytes in *in vitro* mixed glial cultures were studied in 1-day-old mouse cerebral hemisphere. Continuous treatment with either met-enkephalin, a met-enkephalin–naloxone combination or naloxone alone revealed that met-enkephalin caused a decrease in total cell numbers compared with naloxone-treated cultures and controls. These results suggest that the endogenous opioid met-enkephalin suppresses astrocyte growth by a receptor-mediated mechanism.[74]

These results indicate that endogenous opioids act as inhibitory growth factors in neuronal development, probably by inhibition of DNA synthesis. After a single dose of either met-enkephalin or naloxone to 11-day-old rats, DNA synthesis was shown to be increased in the naloxone-treated group but decreased in the met-enkephalin group.[81] Comparing the effects of morphine on DNA synthesis in neonatal rat brain *in vivo* and *in vitro*, it has been shown that morphine inhibits DNA synthesis *in vivo* in animals aged 1–4 days but not in older animals. The *in vivo* effects were blocked by pretreatment with naloxone indicating a receptor-mediated mechanism. Naloxone administered acutely or naltrexone chronically had no effect. Brain tissue incubated with morphine *in vitro*, however, showed no difference in DNA synthesis compared with controls, indicating an indirect mechanism in the control of cell proliferation.[40]

Reduced latencies to tail-flick tests have been demonstrated on day 9 in neonatal rat pups from P1 to P7 when β-endorphin (in doses of 1–50 μg per pup) was administered daily, suggesting hyperalgesia. In these animals, the number of opioid receptors in the brain was reduced when examined on P14.[86] Studies on neonatal rat pups exposed to morphine either *in utero* (pregnant rats given an s.c. morphine pellet on E16) or postnatally (daily injections of morphine 5 mg kg^{-1}) have demonstrated that chronic morphine exposure results in a significant decrease in brain mu receptor density until day 8, gradually increasing to control levels by day 14. These changes were accompanied by tolerance to the analgesic action of morphine, although there was no significant change in delta and kappa receptor densities.[76] An autoradiographic study of neonatal rat brain compared the neuroanatomical pattern of opioid receptor changes in controls and animals treated chronically with morphine. In those receiving morphine from P1 to P4, mu receptor density on P5 was non-existent in parts of the striatum and decreased in other areas such as the amygdala. Longer treatment with morphine from P1 until P8 produced no additional alterations in mu receptor density.[75]

Little is known of the long-term effects of opioid administration in the neonatal period on the developing CNS in humans.

IMPLICATIONS OF BASIC STUDIES

The results from animal experiments suggest that opioid actions differ with age in the neonate, but the early literature is confused, and more studies are required in this area. Prolonged exposure of the newborn rat to morphine has been shown to have an effect on neuronal development and alterations in receptor expression demonstrate the marked plasticity of opioid systems in the rat neonate. However, pain itself in the neonatal period may also adversely affect this development. With the recent increase in the use of opioids in human neonates,[13 62] there is clearly a need to increase our understanding of the development of opioid systems and the factors modulating this development.

Neonatal opioid pharmacology

The pharmacology of opioids in the newborn has been reviewed recently in an excellent article by Hartley and Levene.[28] This article, therefore, examines the current knowledge of the effects of opioid administration in human neonates.

Morphine and semi-synthetic opioids

Morphine, and its semi-synthetic derivatives codeine and diamorphine, rely in part on the production of metabolites for activity. Because of the large variation in pharmacokinetics of these drugs in neonates, metabolite production can be unpredictable.[28] A recent emergence of more sensitive and specific measurements of metabolites using high pressure liquid chromatography has allowed more detailed investigation of the pharmacokinetics of opioids in neonates, but the difficulties in assessing pain in these pre-verbal patients has left us with little knowledge of the analgesic efficacy of the parent drugs and perhaps, more importantly, their metabolites.

MORPHINE

Morphine is a naturally occurring alkaloid derived from the unripe seed pod of the opium poppy.[9] Among paediatric anaesthetists, it is the most commonly used opioid both during and after surgery.[13]

Morphine is metabolized predominantly in the liver to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G).[9] Glucuronidation is facilitated by uridine diphosphate glucuronosyltransferases (UDPGT), a family of isoenzymes of which 11 different forms have been identified.[49] Both M3G and M6G have significant pharmacological properties.[24] M6G is a potent analgesic and respiratory depressant both in humans and in experimental animals,[25 57] but M3G, the predominant metabolite, is thought to be antagonistic to the analgesic effects of morphine and M6G.[70]

The effects of morphine are therefore dependent on the ratio of M6G:M3G produced,[43] and differential maturation of UDPGT enzymes in the premature and term neonate may produce an evolving ratio of M6G:M3G after morphine administration. This may in part explain a large variation in the effects of morphine in neonates. In premature neonates, the M6G:M3G ratio is related inversely to birth weight, and decreases significantly with increasing birth weight and gestational age.[27]

What is the analgesic efficacy of morphine in the neonate? Most research has concentrated on the adequacy of sedation of neonates undergoing ventilation in the intensive care unit. In one such study, comfort scores incorporating both behavioural and physiological variables were used to assess the adequacy of sedation in premature and term neonates requiring continuous morphine infusions during mechanical ventilation for respiratory distress syndrome. There was no significant difference in the correlation between plasma morphine and analgesic effect in these two age groups. Adequate sedation occurred in 50% of patients with a plasma morphine concentration of 125 ng ml^{-1} (95% confidence interval 116–135 ng ml^{-1}).[11] Studies of the analgesic effects of morphine and its metabolites in post-surgical, spontaneously breathing neonates are urgently required before we can adopt a more informed approach to the use of this opioid.

Kupferberg and Way, in 1960,[42] deduced that the increased sensitivity of neonatal rats to morphine was caused by the greater permeability of the blood–brain barrier. A study by Way, Costley and Way in 1965[83] compared carbon dioxide response curves after morphine and pethidine in eight spontaneously breathing neonates before surgery. The authors found that with morphine 0.05 mg kg^{-1} the carbon dioxide response curve shifted to the right to a greater degree than with pethidine 0.5 mg kg^{-1}. The doses were chosen on the assumption that they were equi-analgesic, and no consideration was given to the consequences of maternal pethidine administration (some had pethidine before delivery) in the immediate postnatal period. Although they concluded that morphine was a more powerful respiratory depressant than pethidine, the statistical and clinical significance of these results was not discussed. Early studies such as these have probably done much to enhance the perception that opioids, in particular morphine, are potent respiratory depressants in the neonate and should only be used with extreme caution.

Subsequent studies, however, do not necessarily agree. A retrospective study of the use of opioids in neonates found that 13% of spontaneously breathing neonates developed apnoea or respiratory depression, thought to be caused by opioids.[61] Nineteen percent of these babies received morphine but none developed respiratory complications, all of which were attributable to papaveretum or pethidine. In comparing the respiratory effects of morphine infusions in neonates and children after cardiac surgery, no age-related differences were found, and it was concluded that neonates have the same ventilatory response to morphine as infants and children at the same plasma concentration.[48]

We now have much more knowledge of morphine pharmacokinetics and the activity of its metabolites, and it is possible that if equi-analgesic rather than "scaled-down" adult doses are given, the risk of serious respiratory depression would be no greater.

Studies of morphine use in neonates have not reported any significant cardiovascular side effects such as bradycardia or hypotension.[26 39]

CODEINE

Codeine, or methylmorphine, is a semi-synthetic opioid produced by the substitution of a methyl group for the hydroxy group on carbon 3 of morphine. Ten percent of codeine is demethylated in the liver to form morphine, which is likely to be the main contributor to its analgesic effects.[63] The remainder is demethylated to the inactive norcodeine which is either conjugated or excreted unchanged in urine.

Despite a marked increase in its use among paediatric anaesthetists since 1988,[13 64] data on its kinetics are lacking and we have minimal information on the pharmacodynamics of codeine in neonates. Case reports of adverse reactions such as vasodilatation, severe hypotension and apnoea in infants and children after i.v. administration have precluded its use by this route in all age groups.[68] In the retrospective study of opioid use discussed above, respiratory depression and apnoea occurred in two of 26 spontaneously breathing babies who received i.m. codeine phosphate 1 mg kg^{-1} after operation, although the number of doses was not recorded.[61]

Although there are no data available for neonates, it is likely that immature hepatic metabolic pathways may cause prolonged half-lives of both codeine and subsequently morphine, resulting in an unpredictable quality of analgesia. More research is required if we are to use this opioid effectively.

DIAMORPHINE

Diamorphine is used less commonly than morphine as a sedative for neonates in the intensive care unit, and it is rarely used for postoperative analgesia. Diamorphine is a semi-synthetic opioid produced by the acetylation of morphine. In adults it is deacetylated rapidly in plasma after systemic administration to 6-monoacetyl morphine (6-MAM) by the action of the enzyme plasma cholinesterase, with a half-life of approximately 3 min.[46] 6-MAM is relatively fat soluble and enters the CNS readily where it is probably further de-acetylated to morphine. It is thought that these two active metabolites contribute greatly to the analgesic effect of diamorphine, which is considered to act as a pro-drug.[82]

The effects of diamorphine were studied in 34 premature neonates (gestational age 26–40 weeks) requiring sedation for mechanical ventilation, after a loading dose of 50 $\mu g\ kg^{-1}$ followed by an infusion of 15 $\mu g\ kg^{-1}\ h^{-1}$. A transient decrease in mean arterial pressure was noted at 30 min, coinciding with a statistically significant decrease in heart rate. These effects were not considered clinically significant. However, a significant decrease in ventilatory frequency at 30–60 min was felt to be beneficial in allowing synchrony with the ventilator. This dose regimen provided a mean steady state morphine concentration of 62.6 ± 20.8 ng ml^{-1} and resulted in adequate sedation in all neonates.[16] It was concluded that diamorphine can provide safe sedation for premature neonates undergoing ventilation in the intensive care unit.

Synthetic opioids

Fentanyl, alfentanil and sufentanil are synthetic opioids derived from pethidine. The parent compounds are potent analgesics and their metabolites are either weak analgesics or inactive.[54] As they do not rely on metabolism for activity, they would seem to be a more logical choice of opioid to treat neonatal pain. However, their pharmacokinetics are still very variable in this age group.[28] A low therapeutic index and fears of respiratory depression have precluded their use as postoperative analgesics in spontaneously breathing neonates but they are commonly used during anaesthesia and as sedatives for patients requiring intensive care.

FENTANYL

Fentanyl is a synthetic opioid agonist derived from the phenylpiperidines with an analgesic potency 50–100 times that of morphine. This may be explained by its high lipid solubility and therefore ease of access to the CNS, and after i.v. injection it is distributed widely to the tissues and viscera. In the adult, metabolism is hepatic with less than 6% of the unchanged drug excreted in urine. This is primarily by de-alkylation to norfentanyl but also by hydroxylation of fentanyl and norfentanyl by the isoenzyme system cytochrome P450.[54] A short duration of action and more predictable pharmacokinetics are reasons for its popularity as an analgesic during major surgery and as a sedative in the intensive care unit. A narrow therapeutic index and side effects such as respiratory depression have hampered its use as a postoperative analgesic, both in adults and children.

In order to determine a dose regimen for fentanyl use in neonates undergoing ventilation for respiratory distress syndrome, its effects were compared in 20 newborn and premature neonates with a control group who did not receive fentanyl. The mean dose required to produce adequate sedation was 0.64 $\mu g\ kg^{-1}$ in neonates of less than 34 weeks gestational age, increasing to a mean of 0.75 $\mu g\ kg^{-1}$ in those 34 weeks or older. Mechanical ventilation was tolerated well in the fentanyl group compared with controls, without the need for additional sedation or analgesia. There were no significant cardiovascular side effects in the fentanyl group and no reports of rigidity of the thorax.[66] Interestingly, a significant change in the pharmacodynamic response with time was found in eight neonates requiring sedation during extracorporeal membrane oxygenation for respiratory failure in the first few days of life. The mean fentanyl infusion rate to achieve adequate sedation increased steadily during the 6-day infusion period, with a parallel increase in mean plasma fentanyl concentration. These data suggest that a marked tolerance to the sedative effects of fentanyl occurs in the early neonatal period, and probably reflect opioid receptor desensitization rather than an alteration in pharmacodynamics as a consequence of maturation.[2] Fentanyl may be a beneficial agent for use as a short-term sedative or analgesic in neonates undergoing ventilation, but we need a clearer understanding of its pharmacodynamics.

ALFENTANIL

Alfentanil is an analogue of fentanyl with 10–20% of its potency and a shorter duration of action.[54] Alfentanil is seldom used as an adjunct to anaesthesia in neonates but, because of its favourable pharmacokinetic properties, it is used as a sedative and analgesic in neonatal intensive care.

All data on the pharmacodynamics of alfentanil have been derived from a study of premature neonates undergoing ventilation in the intensive care unit. Twenty premature neonates (gestation 25–36 weeks, ages less than 24 h), undergoing ventilation for respiratory distress received a dose of alfentanil 20 $\mu g\ kg^{-1}$ i.v. over 2 min which produced a rapid and significant decrease in heat rate and arterial pressure and an accompanied decrease in Pa_{O_2}.[52] The same dose, in a matched age group, was noted to result in a "transient" decrease in arterial pressure, heart rate and arterial oxygen tension.[53]

Observing the use of alfentanil before treatment procedures in 20 critically ill neonates undergoing mechanical ventilation, a mean dose of 11.7 (range 9–15) $\mu g\ kg^{-1}$ produced severe muscle rigidity and jerking in four babies which impaired ventilation. EEG recordings of three of these babies showed no increase in seizure activity. Nine babies had mild to moderate rigidity which did not interfere with mechanical ventilation. It was concluded that alfentanil should not be used in neonates without neuromuscular block because of the danger of rigidity.[60]

SUFENTANIL

Sufentanil is another synthetic opioid, a thienyl analogue of fentanyl. It possesses 5–10 times the potency of fentanyl because of a greater affinity for opioid receptors.[54] Despite widespread use as an adjunct to anaesthesia in the USA, it is not as yet licensed for use in the UK. Little has been published on its use in neonates.

Some pharmacodynamic deductions were made in a comparative study of sufentanil in 28 paediatric patients. Neonates were compared with infants, children and adolescents during elective cardiac surgery. After induction of anaesthesia, a single dose of sufentanil 10–15 $\mu g\ kg^{-1}$ i.v. was given rapidly. Anaesthesia with sufentanil was supplemented with nitrous oxide or another opioid if heart rate or mean arterial pressure increased to greater than 20% of baseline values. This occurred at significantly higher plasma sufentanil concentrations in the neonatal group compared with all other groups. It was deduced that neonates may have a decreased sensitivity to the anaesthetic effects of sufentanil, or that an acute tolerance developed. However, patients more than 9 months of age received pethidine, diazepam and pentobarbitone orally as premedication 75 min before surgery, and it is likely that this had a marked effect on the analgesic efficacy of sufentanil.[23]

Conclusions

Although care must be taken in extrapolating data from animals to humans, our knowledge of opioid system development in human neonates has been enhanced by information from animal experiments. Analgesic pathways are anatomically and functionally different in the neonatal compared with the adult rat and display a marked plasticity. Although opioid systems appear very early in fetal life they do not reach adult levels of function for some time. In addition to a contribution to analgesic mechanisms, they probably have other significant roles such as regulation of neuronal development within the CNS.

There is now overwhelming clinical evidence that neonates react adversely to a noxious stimulus, although the extent of their perception of pain in comparison with adults is as yet unknown. This information has prompted a widespread increase in the use of opioids for sedation and treatment of postoperative pain, although our knowledge of their effects in this age group is still far from complete. In particular, too few studies have examined the analgesic potency of opioids in the newborn, and we are ignorant of the longer term consequences of early opioid administration on the ontogeny of opioid systems and subsequent neurological development in humans. Information from animal experiments allows us an insight into possible mechanisms in humans, but the degree to which they can be compared can only be established by a careful analysis of the developmental regulation of opioid function in human infants.

SHORT COMMUNICATIONS

Prevention of hypothermia by cutaneous warming with new electric blankets during abdominal surgery†

Y. CAMUS, E. DELVA, A. E. BOSSARD, M. CHANDON AND A. LIENHART

Summary

We have evaluated the efficacy of new electric warming blankets, which meet the requirements of the international standard for perioperative electrical and thermal safety, in preventing intraoperative hypothermia. We studied 18 patients undergoing abdominal surgery, allocated to one of two groups: in the control group, there was no prevention of intraoperative hypothermia (n=8) and in the electric blanket group, two electric blankets covered the legs and upper body (n=10). Anaesthesia duration was similar in the two groups (mean 201 (SEM 11) min), as was ambient temperature (20.5 (0.1)°C). Core temperature decreased during operation by 1.5 (0.1)°C in the control group, but only by 0.3 (0.2)°C in the electric blanket group (P<0.01). Five patients shivered in the control group compared with one in the electric blanket group (P<0.05). We conclude that cutaneous warming with electric blankets was an effective means of preventing intraoperative hypothermia during prolonged abdominal surgery. (*Br. J. Anaesth.* 1997; **79**: 796–797).

Key words
Surgery, abdominal. Equipment, warming blankets. Temperature, monitoring.

Cutaneous warming is the most effective means of preventing intraoperative hypothermia.[1] Forced-air or electric warming blankets can be used for this purpose.[2] However, until recently, the use of electric blankets was restricted because of concern over electrical hazards and thermal injuries. Electric warming blankets are now available which meet the requirements of international standards for perioperative electrical and thermal safety. The aim of this study was to evaluate the efficacy of intraoperative cutaneous warming with these new electric blankets during prolonged abdominal surgery.

Methods and results

After obtaining local Ethics Committee approval and informed consent, we studied 18 adult patients, ASA I–II. Patients were under-going non-haemorrhagic abdominal surgery in the supine position, lasting at least 2 h, under general anaesthesia. Anaesthetic gases were not actively warmed and i.v. fluids were infused at room temperature. Patients were allocated randomly to one of two groups. In eight patients (control group), no special precautions were taken to prevent hypothermia unless core temperature decreased to less than 35 °C; to avoid more profound hypothermia, cutaneous warming of the legs was then started with a lower body forced-air blanket attached to a forced-air warmer (Bair Hugger model 500E) set on high (air temperature approximately 43 °C). In the other 10 patients (electric blanket group), two electric blankets (Electro Concept) covered the available skin surface: one (model CB2, 110 x 90 cm) over the legs up to the pubis, the second (model CB3, 120 x 40 cm) over the head, trunk and arms. The two blankets were set at 40 °C and a single layer of cotton sheeting was interposed between the skin and blankets to prevent staining, as recommended by the manufacturer. The blankets were placed over the legs as soon as the patient lay on the operating table, and over the upper part of the body after tracheal intubation.

Each blanket is attached to a control box, which is connected to an AC 230 V/50 Hz wall supply. Eight thermal probes, distributed in the blanket, are connected to thermostats located in the control box. The blanket and control box meet the 1996 ISO standards regarding thermal safety, electrical safety, fire protection and mechanical characteristics. Contact skin temperature greater than 41 °C is not permitted. Leak currents in the blankets are <3 μA, although up to 5000 μA are allowed in such products. Each blanket is made of a watertight PVC sheath containing an inner viscose layer with a single electric warming component and weighs 1 kg. The blankets are sponged and disinfected with a solution of benzalkonium chloride.

Ambient temperature was measured by a thermocouple positioned at the level of the patient. Core temperature (T_{core}) was measured at the tympanic site. Skin temperatures were measured at five skin-surface sites (lateral aspect of the arm, thorax,

†Presented in part at the annual meeting of the American Society of Anesthesiologists, New Orleans, October 1996.

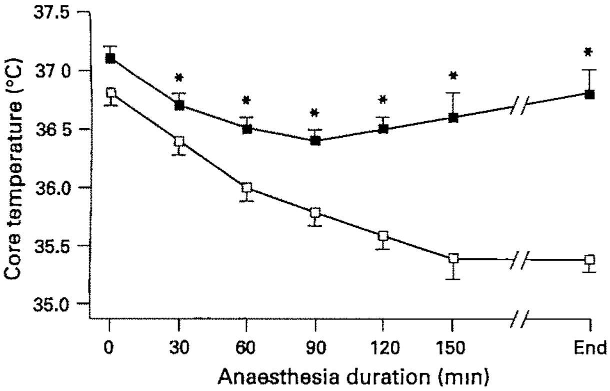

Figure 1 Intraoperative changes in tympanic temperature (mean, SEM) in the control group (□) and in electric blanket group (■). *$P<0.05$ between groups.

thigh and calf, and ventral aspect of the thigh). All temperature probes were attached to electronic thermometers (Mon-a-therm). Temperatures were recorded at 15-min intervals from induction of anaesthesia until core temperature returned to its initial value after operation. The highest skin temperature was noted. During recovery, shivering was evaluated at 5-min intervals by an independent observer blinded to the treatment. The skin was examined carefully in the recovery room for thermal lesions. Data are expressed as mean (SEM) and analysed using ANOVA, the modified *t* test, Fisher's exact test and the unpaired *t* test, as required. $P<0.05$ was considered statistically significant.

The two groups did not differ significantly in age (50 (range 24–65) yr), weight (68 (2) kg), initial core temperature (37.0 (0.1) °C), duration of anaesthesia (201 (11) min), i.v. fluids administered (1.7 (0.1) litre) or operating room temperature (20.5 (0.1) °C). Changes in T_{core} in the two groups are shown in figure 1. In the control group, T_{core} decreased during the first 3 h, then stabilized and was 35.5 (0.1) °C at the end of anaesthesia. T_{core} decreased to less than 35 °C in three of eight patients in the control group and forced-air warming of the legs was started. In the electric blanket group, T_{core} decreased during the first 90 min, but increased thereafter to reach 36.9 (0.2) °C at the end of anaesthesia. Mean T_{core} decreased during operation by 1.5 (0.1) °C in the control group but only by 0.3 (0.2) °C in the electric blanket group ($P<0.01$). The highest skin temperature registered under the blankets was 38.4 °C. During recovery, shivering was observed in five patients in the control group and in one patient in the electric blanket group ($P<0.05$). No postoperative thermal skin lesions were detected.

Comment

After an initial rapid decrease in core temperature caused by internal body heat redistribution, intraoperative core hypothermia results mainly from heat loss exceeding metabolic heat production. Intraoperative skin surface warming is the most efficient means of maintaining patients normothermic as it allows effective heat transfer to the body. For this purpose, the efficacy of both forced-air and electric warming blankets has been demonstrated. However, electric blankets involve electrical hazards as a result of insufficient electric insulation, outer sheath breakage or cutting by surgical instruments, with a risk of electrocution to the patient, surgeon or anaesthetist. Consequently, their use has generally been restricted to the recovery room. International standards (CEI 601–1; CEI 601–1–2; CEI 601–2–35) have been defined recently regarding the requirements for electrical and thermal safety of the warming devices that can be used in the operating room.

In this study, electric blankets which fulfilled these requirements significantly decreased intraoperative hypothermia during abdominal surgery. The limitation of skin warming to guarantee thermal safety could result in a lower efficacy regarding heat transfer. In a previous study, we found the use of a single blanket to be insufficient in keeping the patient normothermic during abdominal surgery.[3] The best method of improving this temperature-related restricted efficacy is to increase the amount of skin surface to be warmed. Abdominal surgery in the supine position allows cutaneous warming of the legs and upper part of the body. This combination produced sufficient heat transfer to keep patients nearly normothermic. The highest skin temperature of 38.4 °C recorded under the electric blankets was well under the limit of 41 °C allowed by international standards. In any case, such skin temperatures are not likely to produce thermal lesions, and none was observed.

Using electric blankets rather than forced-air warming can reduce the cost of intraoperative warming. If fixed costs (depreciation of the main units for a 5-yr lifespan and maintenance by the manufacturers) are similar, the cost of disposable air blankets is much higher than the labour cost of cleaning electric blankets. We estimated that warming therapy in our institution is 2–3 times less costly with electric blankets than with forced-air warming.

In summary, cutaneous warming with electric blankets offers an effective and cost efficient means of preventing intraoperative hypothermia during prolonged abdominal surgery.

Hypnotic effect of i.v. thiopentone is enhanced by i.m. administration of either lignocaine or bupivacaine

M. TVERSKOY, I. BEN-SHLOMO, M. VAINSHTEIN, S. ZOHAR AND G. FLEYSHMAN

Summary

We have compared the hypnotic requirements for i.v. thiopentone alone and in combination with i.m. lignocaine or bupivacaine. Ninety women, ASA I–II, undergoing minor gynaecological surgery were allocated randomly to nine groups of 10 patients to receive thiopentone combined with i.m. lignocaine, bupivacaine or saline, respectively. Thiopentone was administered in bolus doses of 0.5 mg kg^{-1} every 30 s until loss of response to verbal command. Lignocaine and bupivacaine significantly enhanced the hypnotic effect of thiopentone in a dose-dependent manner. The maximum doses tested (lignocaine 3.0 mg kg^{-1} and bupivacaine 1.0 mg kg^{-1}) reduced the hypnotic dose of thiopentone by 39% and 48%, respectively. We conclude that if lignocaine or bupivacaine are injected into soft tissue before induction of anaesthesia by thiopentone, the i.v. dose of the latter should be modified accordingly. (*Br. J. Anaesth.* 1997; **79**: 798–800).

Key words
Anaesthetics i.v., thiopentone. Anaesthetics local, bupivacaine. Anaesthetics local, lignocaine.

The use of local anaesthetic drugs is increasing steadily as local and regional anaesthesia gains popularity and there is a growing interest in the possible interactions of local and regional anaesthesia with drugs used for general anaesthesia.[1–3] Recently, we have documented that bupivacaine-induced spinal block significantly reduced the hypnotic requirements of thiopentone, midazolam and propofol.[2 3] Interestingly, the magnitude of this effect was not uniform for all of these drugs, which suggests an effect additional to and distinct from spinal block. Earlier reports indicated that there was a systemic interaction between lignocaine and general anaesthetics which led to reduction in the requirements for general anaesthetic agents.[4 5] However, administration of either i.v. or aerosolized lignocaine was shown to have no effect on the haemodynamic response to intubation and anaesthesia.[6] The apparent dissociation between the anaesthetic interaction and haemodynamic effect suggests that factors associated with mode of administration may play a role in the degree of synergism displayed between the combined drugs.

A possible effect of local anaesthetics injected into soft tissue is modification of the requirements for general anaesthetics. Not infrequently a dose of local anaesthetic is injected to provide pain relief for surgical procedures but is either insufficient or ineffective. The anaesthetist is then faced with a patient who has already received a dose of local anaesthetic into a soft tissue location, but still has to receive general anaesthesia. The reverse sequence may also occur when regional pain control is used during and after operation. Here, there may be an additional factor in the form of sedatives (functionally related to some of the general anaesthetics) administered in addition to this analgesia. Indeed, in a recent study we found that locally administered lignocaine or bupivacaine significantly reduced the dose of propofol required for induction of anaesthesia.[7]

In order to evaluate the hypnotic interaction between the commonly used i.v. anaesthetic thiopentone and the widely used local anaesthetics lignocaine and bupivacaine, we carried out this prospective, double-blind, dose–response study.

Methods and results

After obtaining informed consent and approval from the Institutional Review Board, we studied 90 women (aged 20–50 yr; ASA I or II; weighing 50–90 kg) undergoing elective minor gynaecological surgery. Patients did not receive premedication and were allocated randomly to one of nine subgroups of 10 women each, divided further into three groups: group 1 (40 patients) received one of four doses of 4% lignocaine i.m. (0.5, 1.0, 2.0 and 3.0 mg kg^{-1}; 10 patients for each dose), administered into the gluteus muscle 10 min before induction of anaesthesia; group 2 (40 patients) received one of four doses of 0.5% bupivacaine i.m. (0.25, 0.5, 0.75 and 1.0 mg kg^{-1}; 10 patients for each dose), administered into the gluteus muscle 30 min before induction of anaesthesia. Thus the volume injected

Table 1 Groups and subgroups of patients in a study on the interaction of i.v. thiopentone and i.m. lignocaine or bupivacaine. Values are mean (SD). $^*P<0.05$ compared with group 3

Group		Lignocaine dose (mg kg^{-1})	Bupivacaine dose (mg kg^{-1})	Thiopentone dose (mg kg^{-1})
1	a	0.5		4.23 (0.64)
	b	1.0		3.37 (0.30)*
	c	2.0		3.16 (0.37)*
	d	3.0		2.70 (0.41)*
2	a		0.25	4.46 (0.68)
	b		0.50	3.37 (0.42)*
	c		0.75	2.94 (0.14)*
	d		1.00	2.29 (0.47)*
3	(Controls)	0.0	0.00	4.42 (0.70)

was 1–6 ml. Intervals between i.m. injection of lignocaine or bupivacaine and i.v. injection of thiopentone were planned in the light of pharmacokinetic considerations regarding injection of these local anaesthetics to skeletal muscle or fat tissue.[8] Group 3 patients ($n=10$) served as controls and received saline 3 ml i.m. into the gluteus muscle 10 min before induction of anaesthesia.

Inability to respond to a simple command was used as the end-point for hypnosis ("open your eyes!", said twice). Thiopentone was administered i.v. over 5 s in bolus doses of 0.5 mg kg^{-1} every 30 s. Response to verbal command was evaluated 25 s after the conclusion of each bolus. The total dose required to achieve loss of response in each patient was recorded.

The physician who administered thiopentone and monitored the response to verbal command was unaware of the type or dose of local anaesthetic (or saline) administered earlier. On completion of the experimental evaluation, anaesthesia was continued and complemented with additional agents, as clinically applicable.

Analysis of variance (ANOVA) was used to evaluate the difference in mean dose for hypnosis between the subgroups of 10 patients. A simple regression analysis was used to evaluate the consistency of the trend. $P<0.05$ was regarded as the threshold for significance.

There were no differences in age or weight between the nine subgroups of 10 patients (ANOVA). No patient complained of local pain at the injection site that lasted for more than a few seconds. The mean dose of thiopentone for hypnosis in group 3 (controls) was 4.42 (SD 0.70) mg kg^{-1}. A progressive reduction in the mean hypnotic dose was noted for both lignocaine and bupivacaine (fig. 1). The lowest doses of lignocaine and bupivacaine tested (0.5 mg kg^{-1} and 0.25 mg kg^{-1}, respectively) did not reduce significantly the hypnotic dose of thiopentone. The first dose of lignocaine which significantly reduced the hypnotic dose of thiopentone was 1.0 mg kg^{-1}, and that of bupivacaine 0.5 mg kg^{-1} (table 1). The highest doses of lignocaine and bupivacaine tested in this study (3.0 mg kg^{-1} and 1.0 mg kg^{-1}, respectively) reduced the hypnotic requirements for thiopentone by 39% and 48%, respectively. When all individual values for each curve were considered, the trend in reduction of thiopentone hypnotic requirements was $r^2=0.751$ and $r^2=0.594$ for lignocaine and bupivacaine, respectively ($P=0.0001$ in both cases). Alternatively, if only the mean thiopentone dose points, corresponding to the 10 patient groups in the curve, were considered, the trends remained significant for lignocaine ($r^2=0.905$; $P=0.013$) and bupivacaine ($r^2=0.938$; $P=0.0067$).

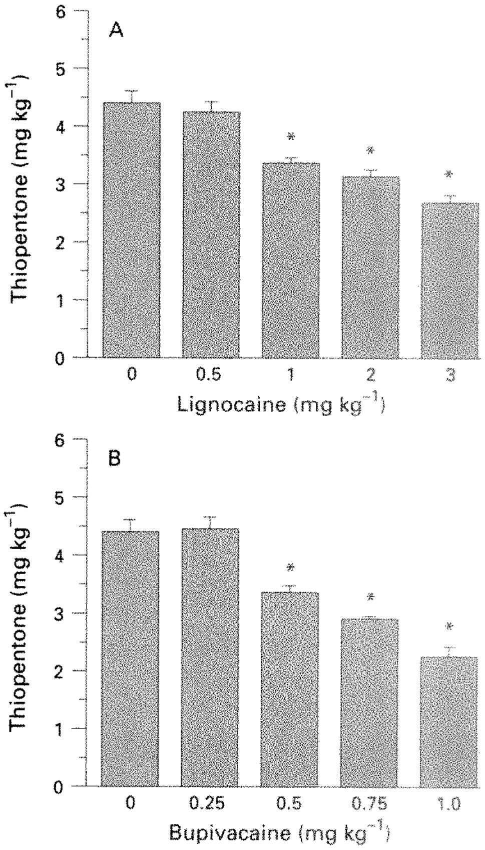

Figure 1 Enhancement of the hypnotic effect of i.v. thiopentone by lignocaine i.m. (A) or bupivacaine i.m. (B). Each point represents the mean (SEM) dose required to achieve loss of response to verbal command in a group of 10 women. $^*P<0.05$.

Comment

The hypnotic dose of thiopentone in the control group in this study (4.42 (0.70) mg kg^{-1}) was within the recommended range for induction of anaesthesia. The highest doses of local anaesthetics tested were less than half the recommended maximum clinical doses.[8] Local anaesthetics are known to have some effects on the central nervous system, which are not unlike some of those of general anaesthetics. Several earlier studies examined the interaction between lignocaine and general anaesthetics;

lignocaine was usually administered i.v. in these studies. In 1982, Kissin and McGee demonstrated that for the hypnotic effect in rats, i.v. thiopentone and i.v. lignocaine were antagonistic[9] at the ED_{50} level, while Phillips and colleagues demonstrated in human patients that lignocaine 250 mg i.v. reduced the anaesthetic dose of thiopentone by 13%.[10] More recent studies indicated that there were no haemodynamic effects for the combination of general anaesthetics and lignocaine.[6] However, these did not examine the hypnotic effect, which may be modified. The difference in magnitude of this enhancement of the hypnotic action of thiopentone, between the formerly described i.v. route of lignocaine administration and the i.m. route of injection that we used for the same drugs (i.e. 13% and 39%, respectively), may reflect a difference in pharmacokinetics between the two routes of administration. However, elucidation of the underlying cause is beyond the scope of our study.

The clinical relevance of our results lies in the growing use of local and regional alternatives for general anaesthesia. Physicians should be alert to the nature of the interaction described in this study. Recently, we found that the two local anaesthetics tested in this study interacted in the same way with propofol,[7] and we are currently investigating their combination with additional general anaesthetics.

Effect of methohexitone and propofol with or without alfentanil on seizure duration and recovery in electroconvulsive therapy

T. T. NGUYEN, A. K. CHHIBBER, S. J. LUSTIK, J. W. KOLANO, P. J. DILLON AND
L. B. GUTTMACHER

Summary

We have studied the effects of methohexitone and propofol with and without alfentanil on seizure duration and recovery in this observer-blinded, prospective, randomized, crossover study involving 24 patients undergoing electroconvulsive therapy (ECT). Each patient had four treatment sessions, and received the following four i.v. regimens in random order: methohexitone 0.75 mg kg^{-1}, methohexitone 0.50 mg kg^{-1} and alfentanil 10 μg kg^{-1}, propofol 0.75 mg kg^{-1}, propofol 0.50 mg kg^{-1} and alfentanil 10 μg kg^{-1}. Additional methohexitone or propofol was given as needed in 10–20-mg increments until loss of consciousness. Suxamethonium 1.0 mg kg^{-1} i.v. was given for muscular paralysis. Mean motor and EEG seizure durations were longer with methohexitone–alfentanil (44.7 (SD 15.0) and 70.5 (29.7) s) than with methohexitone (37.6 (12.6) and 52.6 (15.3) s) and similarly, seizures were longer with propofol–alfentanil (36.8 (15.2) and 54.5 (20.9) s) than with propofol alone (27.2 (11.9) and 39.2 (3.9) s). Seizures were longest with methohexitone–alfentanil and shortest with propofol. Recovery time was statistically shorter in patients receiving propofol compared with methohexitone–alfentanil and methohexitone alone. Alfentanil with a reduced dose of methohexitone or propofol provided unconsciousness and increased seizure duration in patients undergoing ECT. We conclude that the combination of methohexitone with alfentanil is a good regimen for ECT, especially for patients with short seizure duration. (*Br. J. Anaesth.* 1997; **79**: 801–803).

Key words
Analgesics opioid, alfentanil. Brain, convulsions. Anaesthetics i.v., methohexitone. Anaesthetics i.v., propofol. Complications, seizures.

Electroconvulsive therapy (ECT) is a standard method for treating severe depression.[1] Methohexitone and propofol have been used to provide the brief period of unconsciousness needed for ECT[2]; however, both produce a dose-dependent decrease in seizure duration.[3] Although no studies have proved a correlation between seizure duration and clinical outcome, prolonged seizures may be more efficacious[4] and a motor seizure duration of greater than 25 s has been recommended to ensure clinical adequacy of treatment.[5] A further reduction in methohexitone or propofol dose could increase seizure duration but might not provide adequate hypnosis. Alfentanil is a rapid acting opioid with an ultrashort duration of action and no known anticonvusant effect. Combining alfentanil with propofol or methohexitone produces loss of consciousness with a smaller induction dose and thus could potentially increase seizure duration. We compared propofol and methohexitone with or without alfentanil with regard to seizure duration and haemodynamic stability after ECT.

Methods and results

After obtaining IRB approval and informed patient consent, we studied 24 patients, ASA I–III, during a series of four ECT. All patients presenting for a series of greater than or equal to four ECT were enrolled in this crossover, observer- and patient-blinded, prospective, randomized study. Non-invasive arterial pressure, heart rate, electrocardiogram (ECG) and oxygen saturation were recorded at 2-min intervals. Labetalol 20–40 mg was administered before ECT to patients with a history of hypertension. Each patient received the following four i.v. regimens of induction agents in a computer-generated random order: methohexitone 0.75 mg kg^{-1},[2] methohexitone 0.50 mg kg^{-1} with alfentanil 10 μg kg^{-1}, propofol 0.75 mg kg^{-1},[2] and propofol 0.50 mg kg^{-1} with alfentanil 10 μg kg^{-1}. Patients were assessed clinically at approximately 60 s after administration of induction agent and additional methohexitone or propofol was given in 10–20-mg increments if needed until loss of eyelash reflex and response to verbal command. Neuromuscular block

Table 1 Recovery room stay (PACU time) and drug doses for the four regimens (mean (SD)). $P<0.05$ compared with *methohexitone, †methoheitone–alfentanil and ‡propofol

	Methohexitone	Methohexitone–alfentanil	Propofol	Propofol–alfentanil
PACU time (min)	34.0 (88)	35.0 (6.78)	30.5 (5.46)*†	31.8 (5.70)*
Initial dose (mg kg^{-1})	0.75	0.50	0.75	0.50
Total dose (mg kg^{-1})	0.92 (0.25)	0.60 (0.18)*	1.13 (0.52)	0.76 (0.37)‡

was produced with suxamethonium 1.0 mg kg^{-1} i.v. Patients' lungs were ventilated with an air and oxygen mixture during the apnoeic phase. An arterial tourniquet was applied to the right arm of each patient to isolate the right hand for assessment of motor seizure duration. The stimulus was administered immediately after resolution of muscle fasciculations. Five patients received unilateral and 19 patients received bilateral ECT. Two frontal electrodes were placed to record continuous EEG seizure activity using a Thymatron device (Somatics Inc., Lake Bluff, IL, USA). Patients received ECT with 30–50% of the maximum output stimulus depending on the attending psychiatrist's choice. The electrical stimulus used for each patient was kept constant during the study and none required an increase in the stimulus to achieve a longer seizure duration.

EEG seizure durations were determined from the EEG recording at the conclusion of the study by a blinded psychiatrist. Duration of motor seizure was recorded as the time from the beginning to the end of tonic–clonic motor activity in the isolated hand by a nurse who was also blinded to the induction agent used. Anaesthetic dose requirements, duration of stay in the post-anaesthesia care unit (PACU), and heart rate and arterial pressure were also recorded by a blinded nurse. Patients were discharged from the PACU when they met the following criteria: stable haemodynamic and respiratory status, response to verbal commands and ability to move from bed to wheelchair. Mental status was assessed before and after ECT by the same blinded nurse every 5 min until the patient returned to pre-ECT status.

Data were analysed using repeated measures ANOVA for comparison of anaesthetic dose requirements, EEG and motor seizure duration, and duration of stay in the PACU. Data were also analysed by *post-hoc* Student–Newman–Keuls test, where appropriate. $P<0.05$ was considered significant.

Eight men and 16 women, mean age 52 (range 25–80) yr and weight 81 (SD 25) kg (range 55–160 kg) were enrolled in the study for a total of 96 ECT. The doses of methohexitone and propofol with and without alfentanil are listed in table 1. Addition of alfentanil 10 μg kg^{-1} allowed a decrease in induction dose of both methohexitone and propofol by approximately 33%. Thirteen patients (54.1%) required supplementary doses of an induction agent: 46% in the methohexitone group, 54% in the propofol group, 29% in the methohexitone–alfentanil group and 41% in the propofol–alfentanil group. Patients in the methohexitone and methohexitone–alfentanil groups required 23% and 20% increases in their initial dose, respectively, to obtain loss of eyelid reflex and response to verbal command compared with patients in the propofol and propofol–alfentanil groups who required 51% and 52% increases in their initial dose, respectively, to obtain the same response. The ratio between doses of methohexitone and propofol with and without pretreatment with alfentanil were 1:1.27 and 1:1.23, respectively.

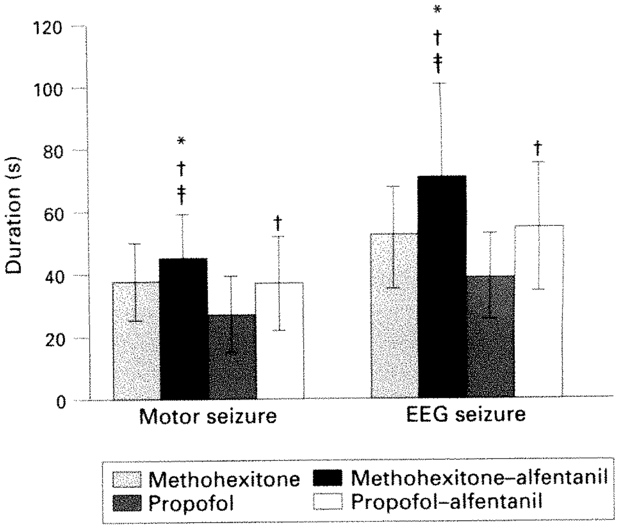

Figure 1 Mean (SD) duration of motor and EEG seizures in the four treatment groups. $P<0.05$ compared with: *methohexitone; †propofol; ‡propofol–alfentanil.

Durations of motor and EEG seizures were longest in the methohexitone–alfentanil group and shortest in the propofol group (fig. 1). Durations of EEG and motor seizures were greater when patients were anaesthetized with methohexitone or propofol in combination with alfentanil than when methohexitone or propofol alone was used (fig. 1). All EEG seizures lasted longer than 25 s except for two of the treatments, performed using propofol alone. PACU duration was significantly shorter in patients receiving propofol or propofol with alfentanil (table 1). Patient mental status (anxiety level, clumsiness, fatigue and drowsiness) at the time of discharge was not affected by the induction agent administered. Alfentanil in combination with methohexitone or propofol had no significant effect on haemodynamic stability.

Comment

Our patients undergoing ECT with reduced doses of methohexitone with alfentanil had a longer duration of EEG and motor seizures than patients anaesthetized with methohexitone or propofol alone or propofol and alfentanil combined. Propofol with alfentanil was associated with longer EEG and motor seizures than propofol alone. This increase in duration of motor and EEG seizures with the addition of alfentanil probably resulted from its additive effect leading to decreased requirements for methohexitone or propofol and the lack of effect of alfentanil on seizures.

A previous study by Weinger and colleagues demonstrated that pretreatment with fentanyl reduced seizure duration compared with a control group in patients undergoing ECT.[6] In contrast, our study demonstrated prolongation of seizure duration when alfentanil was used to decrease the induction dose of methohexitone or propofol.

The doses of methohexitone and propofol in our study were higher than the doses used by Fredman and colleagues.[2] This may be because there were younger subjects in our study requiring higher doses of anaesthetics and different end-points for loss of consciousness between the studies (loss of eyelash reflex in our study in addition to loss of response to verbal commands in Fredman's study). We could not establish a relationship between the dose of anaesthetic agent and seizure duration as there was minimal intra-patient dose variability.

The cardiovascular response to ECT is caused by activation of the autonomic nervous system. Initial parasympathetic activation results in bradycardia that is followed rapidly by sympathetically induced tachycardia and hypertension.[7] Rampton and colleagues[8] compared the cardiovascular response to ECT after administration of either methohexitone or propofol and reported improved haemodynamic stability after administration of propofol. However, in our study, there was no difference in haemodynamic stability between the four groups. The doses of methohexitone and propofol used in our study were tailored individually to achieve adequate anaesthesia for ECT and patients with a history of hypertension were pretreated with labetalol. This could explain the absence of statistical difference in MAP and heart rate between the four groups. None of the patients in all four groups developed arrhythmias or showed ECG signs of myocardial ischaemia.

The small dose of alfentanil (10 $\mu g\ kg^{-1}$) allowed prolongation of seizure duration without adverse opioid side effects such as chest wall rigidity, respiratory depression or nausea and vomiting. Dinwiddie and Isenberg used high-dose alfentanil (25 $\mu g\ kg^{-1}$) which resulted in nausea and vomiting in two of eight patients.[9]

There was a prolongation in duration of stay in the PACU in patients receiving methohexitone or methohexitone–alfentanil. This was probably a result of the increased seizure durations in these patients. Alternatively, the smooth recovery of propofol may have led to earlier PACU discharge as has been demonstrated in patients undergoing outpatient surgery.[10]

Although seizure duration may be affected by many factors such as sex, electrode placement (unilateral or bilateral), applied energy, individual seizure thresholds, previous ECT or concomitant drug therapy, the crossover design of this study should have eliminated potential bias from inter-patient variability.

In summary, using alfentanil to reduce the dose of methohexitone or propofol resulted in a longer seizure duration but no significant effect on recovery in patients undergoing ECT. Psychiatrists' opinions vary regarding the importance of seizure duration. If it is assumed that short seizures may result in reduced therapeutic benefit, then combined methohexitone and alfentanil may be a better regimen for ECT than methohexitone alone, and propofol with alfentanil is a reasonable alternative.

Pharmacokinetics of controlled release morphine (MST) in patients with liver cirrhosis

H. I. M. KOTB, M. Y. EL-KABSH, S. E. S. EMARA AND E. A. FOUAD

Summary

We have studied the kinetic profile of controlled release morphine (MST) in 12 patients with post-hepatitic cirrhosis, caused by HCV and HBsAg, with portal hypertension, given MST 30 mg for endoscopic sclerotherapy and compared the data with those from 10 healthy controls. Plasma drug concentrations were measured in venous blood samples at intervals up to 12 h by high-pressure liquid chromatography (HPLC). Total body clearance (*Cl*) and systemic availability were estimated using a compartmental method. Patients with cirrhosis had less clearance (0.586 litre h^{-1}) than controls (0.729 litre h^{-1}). Mean residence time (MRT) was prolonged in cirrhotic patients (19.57 h) compared with controls (7.03 h). Elimination half-life in cirrhotic patients (mean 7.36 (SEM 0.45) h) was nearly twice that of controls (4.01 (0.15) h). Serum concentrations were higher at all sampling times in the cirrhotic patients (peak concentration 35.2 (3.2) ng ml^{-1} compared with 12.8 (0.4) ng ml^{-1} in controls). For these changes in the kinetic profile of morphine (as MST) in cirrhotic patients, who experienced more sedation than controls, a smaller dose study together with longer dosing intervals is recommended. (*Br. J. Anaesth.* 1997; **79**: 804–806).

Key words
Analgesics opioid, morphine. Liver, cirrhosis. Pharmacokinetics, morphine. Formulations, morphine.

Morphine is metabolized mainly by the liver and its metabolites are excreted via the kidney.[1] Therefore, it might be expected that there are alterations in morphine disposition in patients with liver disease. Investigations have shown both normal[2] and abnormal clearance[3] of i.v. morphine in alcoholic cirrhosis. It was proposed that these differences were related to the severity of hepatic dysfunction in the two groups studied. Blaschke[4] suggested that, as different types of liver disease vary in their relative emphasis on changes in liver cell function, liver blood mass and liver blood flow, so pathological differences may present as a spectrum of altered pharmacokinetics for a given drug. A drug that undergoes clearance by the liver, being mainly flow-dependent, is affected more than a capacity-limited drug under conditions in which liver blood flow is more compromised than hepatocellular function (and vice versa). However, few studies have investigated this hypothesis. Often the term "cirrhosis" has been used as a general description for patients with liver disease, irrespective of aetiology.

Sustained release oral morphine (MST continus: Napp Laboratories) has become popular as an analgesic. However, there have been no studies on its disposition in patients with cirrhosis of the liver. In this study, our aim was to define the pharmacokinetic profile of MST in a group of patients with post-hepatitic liver cirrhosis (Child's classification A and B) compared with a healthy control group.

Methods and results

Institutional approval and patient consent were obtained from 12 patients (mean age 40.3 (35–45) yr; mean weight 65.17 (SD 4.53) kg) who were admitted to the gastroenterology unit of Assiut University Hospital for endoscopic sclerotherapy of oesophageal varices. All were cirrhotic as a result of previous hepatitis C (HCV) or B (HBV) infection. All had normal renal function with normal serum creatinine concentration. None was receiving drugs known to alter hepatic blood flow or hepatic metabolizing enzyme ability and none had previously received morphine or other opioids.

To ensure homogeneity in the cirrhotic patients, serum albumin, serum bilirubin and total protein concentrations were all within the normal range; the albumin to globulin ratio was lower than normal. None of the patients had surgical portocaval shunts and none had clinical evidence of ascites.

The control group comprised 10 fasting healthy subjects (mean age 39.3 (range 35–45) yr; mean weight 65.0 (SD 1.94) kg) with normal hepatic and renal function tests, and negative hepatitis (anti-HCV and BsAg) tests.

Both groups received MST oral morphine 30 mg

and a cannula was inserted into an antecubital vein under local anaesthesia to facilitate sampling of venous blood. Blood was obtained every 30 min for the first 3 h, followed by every hour for the next 3 h, and then every 2 h up to 12 h. Serum concentrations of morphine were measured by high-pressure liquid chromatography (HPLC). Plasma (0.2 ml) was deproteinized with acetonitrile 0.2 ml, and then a portion (50–100 μl) of the supernatant was analysed on an ODS/TM column with a mobile phase of (ml min^{-1}) acetonitrile–methanol–phosphate buffer (20:20:60), pH 6.6 and 0.3% ethylamine. The fluorescence response was measured at excitation and emission wavelengths of 215 and 348 nm, respectively. The limit of quantitation was 2 ng ml^{-1}, with a coefficient of variation of less than 3%.

Data at different times after oral MST 30 mg were fitted to a two-compartment model, and total body clearance and bioavailability were measured. The differential equations of the proposed model were analysed using the MULTI (Runge computer) program.[5]

It was assumed that the steady state volume of distribution (V^{ss}) was almost the same in the two groups, as reported by Mazoit and colleagues.[3] Other variables, including maximum concentration in blood ($C_P$max), and time to reach maximum concentrations (tC_Pmax), were obtained graphically. The linear trapezoidal method was used for determination of the area under the plasma–concentration curve (AUC) and the area under the first moment curve (AUMC) for determination of mean residence time (MRT). The half-life of the elimination phase ($T_{1/2}$) was calculated using the slope of the elimination phase: $T_{1/2}{}^{\beta}=0.693/\beta$.

Plasma concentrations of morphine over the 12-h study are shown in figure 1. There was rapid appearance of morphine in blood within the first 30 min of the study in both controls and cirrhotic patients. In controls, the curve showed a decreasing trend after 5 h of sustained plasma concentrations with no secondary peak. A higher peak was reached in cirrhotic patients with a sustained concentration almost above that in controls over the study period. This decay in serum morphine concentration showed biexponential decay in both groups.

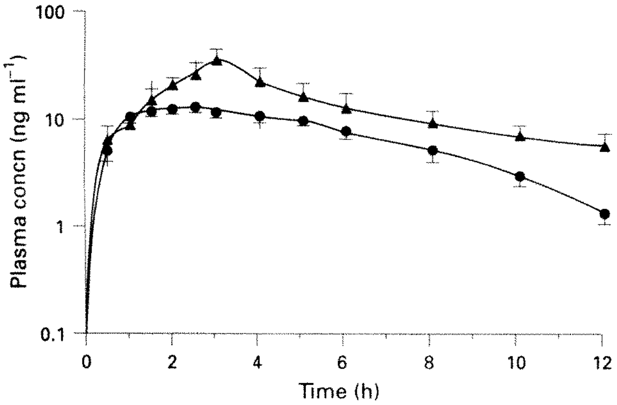

Figure 1 Semi-logarithmic curves representing plasma concentrations of morphine after administration of oral MST 30 mg to normal (●) and cirrhotic patients (▲) (mean, SD).

Table 1 Pharmacokinetics of morphine in normal and cirrhotic patients after oral MST administration (mean (SEM)). All results were significantly different between control and cirrhotic patients (Student's *t* test, $P<0.05$). *These variables were calculated using mean data

Variable	Control oral MST	Cirrhotic oral MST
$C_P$max (ng ml^{-1})	12.81 (0.47)	35.21 (3.24)
tC_Pmax (min)	142.50 (4.91)	174.0 (3.33)
AUC (μg h^{-1} litre^{-1})	92.56 (3.85)	221.33 (33.01)
MRT (h)	7.03 (0.61)	19.57 (0.19)
$T_{1/2}$ (h)	4.01 (0.15)	7.36 (0.45)
*F (%)	16.0	27.7
*Cl (litre h^{-1} kg^{-1})	0.729	0.586

There were significant differences ($P<0.05$) for all kinetic variables studied between the cirrhotic patients and normal subjects (table 1). Cirrhotic patients were over sedated and experienced more side effects than controls.

Comment

We have determined the pharmacokinetics of oral MST 30 mg in normal subjects and cirrhotic patients. Derived kinetic variables in control subjects fitted closely with those reported previously.[6 7]

Patients with severe stable liver cirrhosis, with portal hypertension secondary to viral C and B inflammation, were studied. They received oral MST 30 mg for endoscopic sclerotherapy and showed a three-fold increase in peak concentration of morphine resulting from the reduction in first pass metabolism secondary to reduction in liver cell mass; this led to an increase in the total systemic bioavailability of morphine from 18% in controls to 27.7% in cirrhotic patients. Portosystemic shunting increases the bioavailability of drugs that undergo first-pass effects in the liver. If this is associated with a decrease in hepatic clearance, this may augment the area under the curve and therefore caution is required in administering drugs with first-pass effects to patients with cirrhosis.

In this study, elimination half-lives and total body clearance were significantly altered in cirrhotic patients compared with controls. This clearly reflected the degree of sedation in the cirrhotic patients; however, none developed encephalopathy.

Of particular importance for an oral drug such as MST is the prolonged elimination half-life which depends on total body clearance if repeated doses of the drug are given, as accumulation is more likely to occur. Therefore, for cirrhotic patients who are given MST, a smaller dose together with a more prolonged frequency of administration is recommended.

CASE REPORTS

Subclavian aneurysm causing brachial plexus injury after removal of a subclavian catheter

F. M. WALDEN

Summary

The use of central venous catheters is associated with many different complications, some of which can be life threatening. Most complications associated with the use of central venous catheters are either immediate and occur around the time of catheter insertion, or are delayed and are related to the duration of catheter use. Complications occurring after removal of central venous catheters are reported infrequently but are still a cause of significant morbidity. The following case report illustrates a serious complication which occurred after a large gauge central venous catheter was removed from a patient and demonstrates the importance of close observation not only at the time of catheter placement but also when such devices are removed. (*Br. J. Anaesth.* 1997; **79**: 807–809).

Key words
Complications, subclavian aneurysm. Equipment catheters, central venous. Complications, brachial plexus injury.

Brachial plexus injury is a recognized complication arising from insertion of central venous cannulae. This is not surprising in view of the proximity of the brachial plexus to the subclavian and internal jugular veins and the "blind" puncture technique which is almost universally used. The following case report describes a brachial plexus injury which occurred after removal of a well functioning subclavian catheter which had been inserted uneventfully.

Case report

A 72-yr-old female required plasma exchange for treatment of myasthenia gravis. A triple-lumen 12-French gauge dialysis catheter was inserted under local anaesthetic into the left subclavian vein using the Seldinger technique. The operator (ICU senior registrar), who was experienced in the technique, reported no difficulties during insertion of the catheter and a chest x-ray confirmed a satisfactory position; at no time was there any suggestion of arterial puncture. Intermittent plasma exchange was performed for 6 days during which time the dialysis catheter functioned well.

The catheter was removed by cutting the anchoring sutures and applying gentle traction. Eight hours later the patient complained of left shoulder pain and on examination had a swelling in the left suprascapular region which extended to the left side of the neck. Within 2 h the patient had lost power and tendon reflexes in her left arm.

A magnetic resonance imaging scan showed a mass lesion in the region of the left subclavian artery and compression of the brachial plexus (fig. 1). An angiogram (fig. 2) demonstrated this mass to be a false aneurysm arising from the subclavian artery. The patient underwent urgent surgical repair of the false aneurysm and was discharged home 10 days later, still with residual arm weakness.

Discussion

The use of central venous catheters is associated with a complication rate of 4–35%.[1] Therefore, it is always important to weigh the potential benefits of central venous cannulation against these known risks.[2] Venous dialysis catheters and other large gauge venous access devices are used with increasing frequently in modern day anaesthetic and intensive care practice. Insertion of such devices which are normally only used for sick patients is a highly specialized skill and should be reserved for experienced operators if the complications ascribed to such devices are to be minimized.[3]

Arterial complications occurring after removal of central venous catheters include arteriovenous fistulae[4 5] and vertebral artery aneurysm.[6] These have occurred several days after removal of the catheter and after difficult insertions. A subclavian aneurysm developing immediately on removal of a dialysis catheter has not been described previously, nor has brachial plexus damage caused by such an aneurysm expanding. This case is also unusual in that the aneurysm occurred after uneventful insertion, after 6 days of satisfactory use and immediately after removal.

Arterial damage caused by central venous cannulation is well recognized, the majority of these complications occurring at the time of insertion.[7] However, complications occurring after removal of central venous catheters, while being less common,

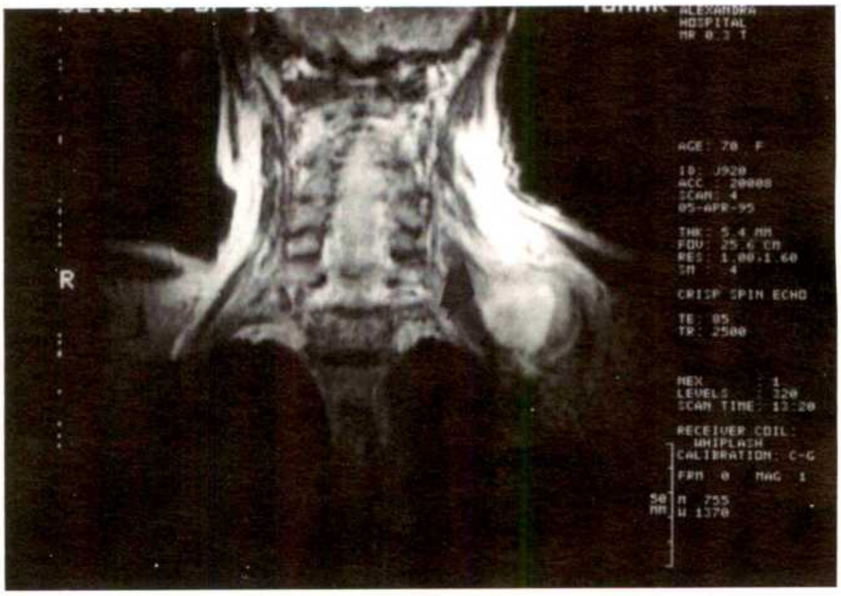

Figure 1 Magnetic resonance imaging scan of the left shoulder illustrating (arrow) 5 cm mass lesion in the left supraclavicular fossa.

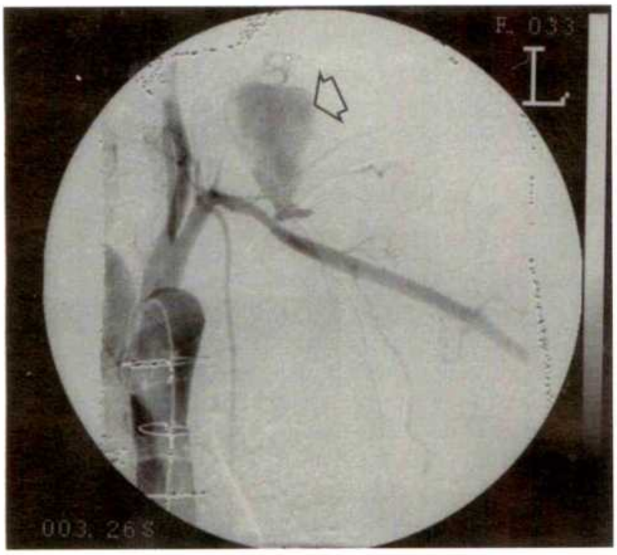

Figure 2 Arch aortogram demonstrating the false aneurysm, 4 cm in diameter (arrow), arising from the left subclavian artery, 4 cm distal to the origin of the vertebral artery.

are still a source of significant morbidity.[8 9] Unlike the current case report, late complications have usually followed difficult insertion and have occurred several days after the catheter was removed. Brachial plexus damage has been reported previously as being caused from direct trauma to the nerves by the insertion needle, guidewire or cannula, or indirectly from expanding haematomas as a result of accidental arterial puncture at the time of insertion.

Because the catheter had functioned well up until the time of removal, it is unlikely in this case to have migrated from the subclavian vein into the artery during use. While many explanations can be proposed, we postulate that it is likely that damage had occurred to the arterial adventitia during insertion or use which was not apparent so long as the catheter had remained *in situ* because of a "tamponading" effect by the catheter on the damaged artery. Only on removal of the catheter and release of the "tamponade" did the integrity of the arterial wall fail resulting in aneurysm formation. Such damage to the adventitia would not have been apparent at the time of insertion because the arterial lumen was not entered and could have occurred either from grazing of the artery by the insertion needle or guidewire, or from rubbing of the catheter on the arterial adventitia during its use.

Complications of central venous cannulation are sought and excluded at the time of catheter insertion and use, by routine chest x-ray after insertion and at intervals thereafter, frequent use of ECG monitoring and close nursing observation of the patient, catheter site and position. Late complications such as infection and catheter migration are similarly well detected and reported. It is of interest however that complications[4–6] after removal of central venous catheters are infrequently, if ever, reported. This may be in part because such complications are not so aggressively sought (and therefore are less frequently detected), despite the significant morbidity associated with such complications, as demonstrated by this and other case reports.[8 9]

This report highlights the fact that removal of central venous catheters is associated with complications, as is their insertion. We recommend a period of close observation and examination of each patient after removal of such devices.

Anaesthesia for laparoscopic cholecystectomy in a patient with Eisenmenger's syndrome

M. S. SAMMUT AND M. L. PAES

Summary

We describe the management of a patient with Eisenmenger's syndrome presenting for laparoscopic cholecystectomy. Of prime concern was maintenance of systemic vascular resistance and this was achieved using infusion of noradrenaline started before induction of anaesthesia and continued after operation. Avoidance of other factors that could potentially increase right to left shunt flow contributed to the successful outcome. (*Br. J. Anaesth.* 1997; **79**: 810–812).

Key words
Complications, Eisenmenger's syndrome. Anaesthesia, general. Surgery, laparoscopy.

In 1897, Eisenmenger first described post-mortem evidence of pulmonary vascular disease in the presence of a large ventricular septal defect and right ventricular hypertrophy.[1] This became known as Eisenmenger's complex. The syndrome was redefined in 1958 by Wood to imply pulmonary hypertension at the systemic level caused by high pulmonary vascular resistance with reversed or bidirectional shunt via a large ventricular septal defect.[2] The actual position of the shunt is immaterial. Indeed, Eisenmenger's syndrome includes any condition in which communication between the pulmonary and systemic circulations gives rise to pulmonary vascular disease causing a right to left shunt.[3] Surgical correction of the original defect merely exacerbates the pulmonary hypertension and may precipitate right ventricular failure.

With improved management of congenital cardiac disease, Eisenmenger's syndrome is becoming very rare. However, these patients occasionally present for incidental non-cardiac surgery. We describe the successful management of a patient with this syndrome presenting for laparoscopic cholecystectomy.

Case report

A 46-yr-old woman was scheduled for laparoscopic cholecystectomy. Cardiac catheterization at 5 yr of age revealed a small ventricular septal defect (VSD) and severe pulmonary hypertension, greater than systemic pressure. In the following years she was admitted on several occasions with pulmonary infections which were treated without mishap. Cardiac catheterization at 26 yr of age showed a VSD with severe pulmonary hypertension and a right to left shunt. The main pulmonary artery pressure was 116/70 mm Hg, aortic pressure was 110/80 mm Hg and pulmonary vascular resistance was approximately 85% of the systemic level. With the patient breathing 100% oxygen, pulmonary vascular resistance decreased by 50% but right ventricular and pulmonary arterial pressures remained unchanged. A year later she underwent a full-term pregnancy with forceps delivery under extradural analgesia and was later transferred to the regional cardiac unit for post-partum monitoring. Apart from a few episodes of desaturation that responded to fluid replacement, recovery was uneventful.

She was in full-time employment at the time of surgery and was not receiving any medication apart from analgesics for gall bladder pain. She complained of shortness of breath on climbing stairs but could manage decorating her own house. On examination she was slim, not obviously cyanosed and showed no clubbing. She had no signs of increased jugular venous pressure, heart rate was 80 beat min^{-1} and arterial pressure was 120/80 mm Hg. There was right ventricular lift, and auscultation revealed a grade III systolic murmur and loud second sound. The lungs were clear. Preoperative echocardiogram showed a hypertrophied right ventricle with good function and a right to left shunt through a small VSD. The electrocardiogram showed right axis deviation with a right ventricular strain pattern and occasional ventricular ectopic beats. Preoperative chest x-ray was reported as normal.

The operation was scheduled for the afternoon and diazepam 10 mg was given in the morning as premedication. Antibiotic prophylaxis for endocarditis included teicoplanin 400 mg and gentamicin 80 mg as she was allergic to penicillin. Heparin was given subcutaneously and continued twice daily.

On arrival in the anaesthetic room, peripheral oxygen saturation (Sp_{O_2}) was 90% breathing air.

M. S. SAMMUT, MRCP, FRCA, FFARCSI, M. L. PAES, FRCA, Department of Anaesthesia, Freeman Hospital, Freeman Road, High Heaton, Newcastle upon Tyne NE7 7DN. Accepted for publication: July 16, 1997.

This was similar to values measured previously on the ward. Breathing oxygen 5 litre min^{-1} via a face mask, this increased to 99%. Midazolam 2 mg was given and direct arterial and central venous pressure monitoring was established. Before induction, an infusion of noradrenaline 0.05 μg kg^{-1} min^{-1} was started. Fentanyl 100 μg and etomidate 18 mg were used to induce anaesthesia and neuromuscular block was achieved with vecuronium. Anaesthesia was maintained with 1–2% enflurane and oxygen enriched air ($F_{I_{O_2}}=0.4$) and additional doses of fentanyl to a total of 250 μg.

Shortly after transfer to theatre, arterial pressure decreased from 130/80 to 95/40 mm Hg with a decrease in oxygen saturation to 94%. Infusion of noradrenaline was increased to maintain systemic pressure. There appeared to be a direct correlation between systemic pressure and oxygen saturation and it was necessary to maintain arterial pressure at 160/90 mm Hg to keep oxygen saturation greater than 97%. When surgery was underway this was achieved with low doses of noradrenaline (range 0.03–0.1 μg kg^{-1} min^{-1}). The increase in end-tidal carbon dioxide after pneumoperitoneum was countered by increasing the frequency of ventilation rather than tidal volume. Intra-abdominal pressure was maintained at less than 15 mm Hg and a head up tilt of 10° was allowed.

Surgery was uneventful and on completion neuromuscular blocking agents were antagonized with neostigmine and glycopyrronium. The trachea was extubated and she was transferred to the intensive care unit, as planned, for postoperative monitoring. The noradrenaline infusion was weaned gradually to a small maintenance dose of 0.03 μg kg^{-1} min^{-1} and this was eventually stopped 20 h later when she was discharged to the surgical ward. Postoperative analgesia was provided by morphine i.v. using a patient-controlled delivery system (PCA). Unfortunately, this was responsible for an episode of hypoxaemia and hypercapnia during the first postoperative night after which non-steroidal analgesic agents and paracetamol were used instead.

During walking she complained of shortness of breath on minimal exertion. These episodes were accompanied by decreases in $S_{P_{O_2}}$, as indicated by pulse oximetry, and responded to oxygen by face mask. Her postoperative haemoglobin concentration was noted to have decreased to 8.9 g dl^{-1} from a preoperative concentration of 17.2 g dl^{-1}. This was most likely the result of slow persistent blood loss from the raw gall bladder bed. Plasma-reduced blood 2 u. were transfused and symptoms improved. She was discharged home 2 days later, 8 days after operation.

Discussion

The theoretical risks of anaesthesia in patients with Eisenmenger's syndrome are considerable. The dangers of a decrease in systemic vascular resistance and subsequent increase in right to left shunt are well described. However, it has also been suggested that these patients do well with a variety of techniques.[4] Nevertheless, there is agreement that the cornerstone of safe anaesthesia in such patients is maintenance of preoperative levels of systemic vascular resistance.[5] Bird and Strunin anticipated the almost inevitable decrease in systemic vascular resistance at induction by administering a small dose of metaraminol during preoxygenation. Unfortunately, this led to hypertension and bradycardia followed by a sudden decrease in oxygen saturation remedied by administration of atropine.[6] To avoid this we opted for a noradrenaline infusion which provided easy and accurate control of arterial pressure, especially important during different levels of surgical stimulation.

The uninterrupted feedback provided by direct intra-arterial pressure monitoring was essential but we decided not to use a pulmonary artery flotation catheter. We reasoned that the risks of misdirection into the left ventricle and cardiac arrhythmias outweighed the possible benefits in this particular case given the general condition of the patient and good biventricular function identified by echocardiography. The site of communication between the pulmonary and systemic circulations also implied that the data obtained could have been misleading.[5]

An opioid-based premedication has been shown to be safe[4] but we chose a benzodiazepine to avoid the risk of preoperative respiratory depression, hypoventilation and hypoxaemia which might have precipitated a cyanotic crisis. On arrival in the anaesthetic room, $S_{P_{O_2}}$ was 90% but delivery of oxygen by a simple face mask with a flow of 5 litre min^{-1} improved this to 99%. Hypoxaemia caused by right to left shunt is not usually reversible by oxygen therapy. Although pulmonary hypertension in this patient was greater than systemic levels, the improvement in $S_{P_{O_2}}$ may be explained by a vasodilator response of the pulmonary vasculature to oxygen with improvement in pulmonary arterial flow and decreased flow across the shunt. This had been demonstrated previously during cardiac catheter studies when this patient was 26 yr old. We were somewhat surprised that this element of reversibility had been maintained.

Problems associated with anaesthesia for laparoscopic procedures pose a higher risk in patients with Eisenmenger's syndrome. Insufflation of the peritoneal cavity with carbon dioxide causes an increase in end-tidal carbon dioxide Acidosis, arrhythmias and hypotension may follow, all of which can precipitate a shunt crisis. Equally, efforts to maintain normocapnia are often accompanied by increased pulmonary airway pressures, particularly as intra-abdominal pressure increases. The effect of this is to increase pulmonary vascular resistance further. The situation may be made worse if the Trendelenburg position is adopted during surgery. Fortunately, a slight head-up tilt is often the requirement for cholecystectomy, as in this case. Other possible complications associated with this type of surgery include pneumothorax and gas embolism. The latter is particularly important because of the direct route available, via the shunt, to the systemic circulation.

Early tracheal extubation in these patients is preferable because of the deleterious effect of positive pressure ventilation, and intraoperative analgesia is thus best provided by short-acting opioids. Although it is not our usual practice to provide patient-controlled analgesia after laparoscopic cholecystectomy we felt that it was justified in this patient in order to mimimize stress in the early postoperative period. We were disappointed that it marred an otherwise uneventful immediate postoperative phase and wonder if the intensive care setting may have encouraged over zealous use of the PCA system with subsequent respiratory depression.

The increase in exertional dyspnoea noted after operation seemed to be directly related to the decrease in haemoglobin concentration. The fact that symptoms resolved after transfusion strengthened that view. The pathophysiology involved, however, is more contentious. In non-cardiac patients acute anaemia is associated with a decrease in the oxygen carrying capacity of the blood and an initial decrease in oxygen flux. The resultant tissue acidosis causes compensatory peripheral vasodilatation and increase in cardiac output. Anaemia may also contribute to a decrease in blood viscosity which reduces further peripheral vascular resistance.[7] In patients with Eisenmenger's syndrome the dynamics are inevitably more complex. Unfortunately, without the benefit of further invasive investigation in this patient the relative importance of these mechanisms and their effect on flow across the shunt remain speculative.

CORRESPONDENCE

Ropivacaine test dose in extradural anaesthesia

Morton and colleagues[1] have described the use of 0.75% ropivacaine for extradural anaesthesia, and in the process have clearly demonstrated the unsuitability of this agent as a test dose. The aim of an extradural test dose is to identify inadvertent i.v. or intrathecal catheter placement. It should have high sensitivity, but produce symptoms that are safe. Morton and colleagues inadvertently administered large i.v. doses of ropivacaine to two patients, despite negative test doses of ropivacaine 22.5 mg. This is not surprising, as Scott and colleagues[2] gave 10 mg min^{-1} i.v. for up to 15 min before producing symptoms. We do not, however, suggest the use of a larger dose of ropivacaine as a test dose. While this may increase sensitivity in identifying vascular cannulation, dangerously high spinal anaesthesia may result in intrathecal injection. Wahedi, Nolte and Klein[3] have produced safe spinal anaesthesia with 0.75% ropivacaine 22.5 mg in non-pregnant subjects, but there are no data to clarify a safe maximum intrathecal dose of ropivacaine in the obstetric population.

The most sensitive pure local anaesthetic test dose for identifying intravascular injection of which we are aware is lignocaine 1 mg kg^{-1}, proposed by Michels, Lyons and Hopkins.[4] However, Richardson and Wissler[5] described abrupt and life-threatening high spinal block after intrathecal test doses of only 45 mg of lignocaine in two patients. Michels' test dose is therefore clearly potentially dangerous.

In summary, we suggest that it is not possible to use a pure local anaesthetic test dose of sufficient dosage to identify the intravascular space without producing dangerously high spinal anaesthesia if injected intrathecally. We see no alternative but to use separate agents to identify inadvertent intravascular or intrathecal injection. Intrathecal catheter placement can be excluded easily using bupivacaine 10 mg. We remain unconvinced of the sensitivity and specificity of adding adrenaline to this test dose, and indeed have some concerns over its safety. Perhaps the addition of a potent short-acting opioid such as remifentanil warrants some investigation in this role? The final logical but somewhat cumbersome suggestion is to follow a negative intrathecal test of bupivacaine with a second test of lignocaine 1 mg kg^{-1}.

Sir,—We thank Drs Dresner, Adams and Klein for their interest in our article. We agree that ropivacaine 22.5 mg is an unsuitable test dose and we should have given greater emphasis to this in our article. But we do not think that this could have been predicted by the work of Scott and colleagues.[1] Our test dose was given over 20 s, considerably faster than the 10 mg min^{-1} used by Scott and colleagues. We do not agree that intrathecal catheter placement can be *easily* (our italics) excluded with bupivacaine 10 mg. Prince, Shetty and Miles[2] compared plain bupivacaine 8 mg by the subarachnoid and extradural routes, and could only discriminate reliably between the two routes by testing straight leg raising after 10 min. We do not agree with the suggestion of adding remifentanil to the test dose; this would seem to be exchanging the known risks and limitations of current test doses for the unknown.

Our own routine practice is to use lignocaine 80 mg as a "test dose". It is our opinion that this dose, if given rapidly, elicits symptoms of early systemic toxicity. We acknowledge that the addition of adrenaline 1 in 200 000 may increase sensitivity and specificity. The potential for high subarachnoid block is real but at least there is early clear evidence of inadvertent subarachnoid placement of the catheter. The crucial point about test doses, and one we continually emphasize to our trainees, is that a complacent attitude to a negative test dose is dangerous; a negative test dose does not completely exclude misplacement of the catheter. When an aspiration test and a test dose are negative, large doses of local anaesthetic must still be given slowly. We believe that this, and the lower toxicity of ropivacaine compared with bupivacaine, is why the two patients in our study who received accidental i.v. injections did not come to serious harm.

Use of inhaled nitric oxide in the critically ill

Sir,—We read with interest the article by Cuthbertson, Stott and Webster on the increasing use of inhaled nitric oxide (iNO) in the critically ill.[1] We would disagree with their statement that there is no evidence that iNO improves patient outcome. One study in neonates with persistent pulmonary hypertension[2] demonstrated a reduction in the need for extracorporeal membrane oxygenation (ECMO) from 71% of patients in the control group to 40% in those receiving iNO (P=0.02). There was no difference in mortality between the two groups (7.1% in the control group *vs* 6.6% in the iNO group). A study of iNO in neonates with hypoxic respiratory failure[3] also demonstrated a decrease in the use of ECMO from 54.5% in controls to 38.6% in those receiving iNO (P=0.014). Again, mortality was similar (16.5% in the control group *vs* 14% in the iNO group). ECMO is expensive, invasive and unavailable in many centres. It is associated with morbidity, but has been shown to reduce mortality in term neonates with respiratory failure.[4] Using iNO to reduce the use of ECMO would seem appropriate. The children involved in studies of iNO are assessed neurodevelopmentally at 18–24 months, which may provide further support for the use of iNO. We accept that it would be wrong to extrapolate the studies directly to adults, although they indicate that there is a real role for iNO, and we await studies in older children and adults to resolve the place of iNO in these groups.

NO is stored as 1000 ppm in nitrogen, an asphyxiating mixture In most units, iNO is added distally to the ventilator without oxygen monitoring. This is potentially dangerous. Providing less than 80 ppm of NO is used, as recommended by Cuthbertson, Stott and Webster, depression of $F_{I_{O_2}}$ is less than one-tenth of the administered $F_{I_{O_2}}$. This requires that the inspired NO concentration should be measured at all times, as they recommend, to ensure that no more than NO 80 ppm is given. NO is also available at varying lower concentrations for use in calibration of monitoring equipment. If a cylinder containing 200 ppm is used to provide an inspired NO concentration of 80 ppm, depression of $F_{I_{O2}}$ is 40% of the set $F_{I_{O_2}}$

We consider that the risks of administering a hypoxic mixture using NO are real but they have been supplanted by concerns about only NO and the higher oxides rather than its nitrogen carrier. It is important that those who use iNO appreciate all of these risks.

4. Field DJ for the UK Collaborative ECMO Trial Group. UK collaborative randomised trial of neonatal extracorporeal membrane oxygenation. *Lancet* 1996; 75–82.

Sir,—Our article was specifically on the use of inhaled nitric oxide (iNO) therapy in adults. Although the data regarding extracorporeal membrane oxygenation (ECMO) in neonates with respiratory distress syndrome and hypoxic respiratory failure are interesting, it does not change our statement that there is no evidence that iNO improves outcome.[1 2] Both studies quoted demonstrated a reduction in the requirement for ECMO but there was no change in mortality. It would be wrong to extrapolate the results in neonates to adult practice. Until further studies have been reported it would not seem appropriate to use iNO therapy merely to decrease the requirement for ECMO.

We have difficulty in understanding the points raised regarding NO delivery. Our article recommended continual monitoring of iNO therapy and a maximum dose. We did not recommend the use of any other cylinder except NO 1000 ppm in nitrogen. If the authors have 200-ppm cylinders designated for "use in calibration of monitoring equipment", we presume they would not be using them for patient care thus eliminating the danger of depression of $F\text{I}_{O_2}$ to which they refer. If iNO therapy and response to therapy are monitored closely and 1000-ppm cylinders are used, we feel that the risk of delivery of hypoxic gas mixtures is minimal.

We are pleased that Drs Whitehead and Baines are in agreement with us that the users of iNO therapy must appreciate all the incumbent risks and potential benefits. It was with this aim that we undertook our survey and made our recommendations based solely on adult practice.

Management of the airway and ventilation during resuscitation

Sir,—In their recent article on the management of the airway and ventilation during resuscitation, Gabbott and Baskett mentioned an intubation aid used to confirm tracheal intubation called SCOTI.[1] I would like to point out that SCOTI (Sonomatic confirmation of tracheal intubation) was first marketed by Penlon in April 1995. This was in response to a need for a device capable of providing "instant" confirmation of tracheal intubation and against a background of ever increasing risk of litigation against anaesthetists. Although the device generated a great deal of interest, sales proved disappointing and at the end of 1996 a commercial decision was taken to discontinue marketing the SCOTI device. I believe a similar device continues to be available in the USA, although I am not aware of any devices working on a similar sonomatic principle being marketed elsewhere.

I trust this information is of interest and clarifies the current position regarding the SCOTI device.

Weaning: is the work of breathing via a tracheostomy tube similar to that via a tracheal tube?

Sir,—Both the editorial by Shneerson[1] and a letter by Bapat and Verghese[2] highlight interesting aspects on difficult weaning from ventilation. While agreeing fully with the main message of the letter[2] which emphasizes the advantages of cuff deflation to facilitate weaning, I have reservations about the comment made on the work of breathing in spontaneously breathing patients.

It is logical to assume that a decrease in peak intrapleural pressure to approximately -15 mm Hg from a normal value of -2.5 to -6 mm Hg while breathing normally through a tracheal tube of 9.0 mm internal diameter (id) reflects an increase in the work of breathing. But is it appropriate to extrapolate this observation and assume that a tracheostomy tube of size 8.0 or 9.0 mm id produces changes of similar magnitude? Work of breathing is dependent mainly on three factors: elastic resistance of the lung; non-elastic viscous resistance; and resistance to air flow. Increase in the work of breathing caused by airway instrumentation is generally believed to be a result of the increase in air flow resistance, even though one study could not confirm this.[3] While it is true that resistance to flow via a tube is dependent much more on internal diameter than on length, halving the length of a tube can reduce resistance by up to 50%[4] and doubling the length can double the resistance.[5] This holds true when flow is laminar. (The relationship between the length of a tube and resistance encountered is complex and there is no analogue for Poiseuille's law in the case of turbulent flow.) The length of a size 9.0 mm id tracheostomy tube is 10.5 cm (Portex, profile cuff type) compared with tracheal tubes cut at 21–24 cm. However, firm conclusions on the work of breathing in tracheostomized patients can only be made from clinical investigations, and not from simple application of mathematical formulae.

Another point worth mentioning is that if a patient starts speaking soon after deflation of a tracheostomy tube cuff without closing its external orifice, there may be a plug of mucus partially obstructing the tip of the tube. This is probably one of the causes of a dramatic improvement of any patient after removal of a tracheostomy tube or extubation!

Resistance. In: *Physics for the Anaesthetist*, 4th Edn. London: Blackwell, 1987; 240–261.
5. West JB. Mechanics of breathing: Airway resistance. In: *Respiratory Physiology—the Essentials*, 4th Edn. Baltimore: Williams and Wilkins, 1990; 101–107.

Sir,—We appreciate Dr Kodakat's interest in our comments. The main objective of our letter was to emphasize that a tracheal tube or a tracheostomy tube increases the workload of breathing relative to the normal respiratory tract.

The peak flow rate of a normal subject at rest is 0.3–0.5 litre s^{-1}. Flow rates greater than 0.25 litre s^{-1} via a tube of less than 10.0 mm internal diameter (id) are turbulent.[1] Therefore, Poiseuille's equation which deals with laminar flow can only be used partially to deduce flow characteristics during intubation. The diameter, length, curvature and material of a tube affect its flow resistance, and thus different tracheostomy tubes, even of similar size and diameter, may have different flow resistances.[2]

To achieve normal ventilation, work is performed to overcome the elastic and frictional impedances of the lungs and chest wall. In the presence of increased resistance or decreased compliance, a greater swing in pleural pressure is required to achieve a given tidal volume, thus increasing the work of breathing.[3] Respiratory muscle fatigue does not occur during quiet breathing but develops when the ventilatory work load is increased. In patients with respiratory distress an inappropriately heightened respiratory drive places excessive stress on the respiratory muscle pump and predisposes to fatigue.[4] The peak flow in such patients could easily increase to 1 litre s^{-1}, resulting in a markedly increased flow resistance with increasing flow rate in a non-linear manner, and could add substantially to the total work of breathing.[5] In this group of patients, intrapleural pressure could even be greater than −15 mm Hg. In contrast, in patients with severe respiratory muscle weakness, changes in intrapleural pressure could be smaller. However, both groups of patients may benefit from a reduction in respiratory resistance caused by cuff deflation.

We agree that for a given patient the work of breathing through a tracheostomy tube would be less compared with an equal diameter tracheal tube. There are no comparative studies of the effect of different sized tracheal tubes or tracheostomy tubes on intrapleural pressure in patients with respiratory failure. Our comment that "changes in intrapleural pressure caused by a size 8.0 or 9.0 mm id tracheostomy tube could be similar to that of a size 9.0 mm tracheal tube" was based on these factors. It was not meant that different sized tubes or tracheostomy tubes have the same flow resistance.

Continuous intra-arterial blood-gas monitoring

Sir,—After reading the study on the usefulness of continuous intra-arterial blood-gas monitoring in patients undergoing thoracic procedures,[1] I feel it necessary to comment on some of the issues raised by the investigators.

The authors stated that the Paratrend 7 (PT7) blood-gas monitoring system has been validated by only one set of investigators in collaboration with the manufacturer. I would like to draw their attention to a multicentre study from North America[2] independently validating the PT7 system. Second, it is stated that a broad range of pH, $P\text{CO}_2$ and $P\text{O}_2$ values were not evaluated in the original studies. I would like to point out that a similar range of pH (7.1–7.57), $P\text{CO}_2$ (2.65–6.85 kPa) and $P\text{O}_2$ (8–68 kPa) values have been evaluated in an earlier study by Venkatesh, Clutton-Brock and Hendry.[3]

The accuracy of the base excess and bicarbonate calculations are a function of the algorithm built into the blood-gas analyser and the monitor and accuracy of $P\text{CO}_2$ measurement. Dissociation in accuracy between the two methods for those two variables may be a reflection of differences in the algorithm or accuracy of the $P\text{CO}_2$ measurement.

While discussing the accuracy of the PT7 and blood-gas analyser, it is stated that "the accuracy and variability of blood-gas analysers are not known exactly". Studies by Hansen and colleagues, and Metger and colleagues have clearly demonstrated the bias and precision of blood-gas analysers when measuring blood-gas tensions in blood.[4 5] The authors have alluded to several factors which influence the accuracy of blood-gas analysis. Even controlling for the factors listed, the accuracy and reproducibility of blood-gas analysers remains an issue. It must be remembered that most blood-gas analysers do not use primary quality control material such as tonometered blood. This significantly limits any conclusions which can be drawn on the accuracy of an intravascular device. While studies such as these are important, clinical outcome and cost effectiveness studies are the ones which will influence the wholesale acceptance of intravascular sensing devices.

5. Metger LF, Stauffer WB, Krupinski AV. Detecting errors in blood gas measurements by analysis with two instruments. *Clinical Chemistry* 1987; **33**: 512–517.

Sir,—I read with interest the article by Zollinger and colleagues[1] independently confirming the good clinical performance of the Paratrend 7 (PT7) multiparameter intra-arterial blood-gas monitoring system first described by this institution.[2–5] Several points raised by the article require further discussion. The authors gave the impression that the sensor may be re-calibrated when inserted into a vessel by using data from a bench top blood-gas analyser. This is incorrect. Comparison between values obtained with the PT7 and bench top analyser can be made and the original calibration curve adjusted in the light of this comparison; this is somewhat different to re-calibration. When inserted into a vessel it is not possible to recalibrate the sensor without loss of sterility. The authors also stated that the PT7 can measure blood-gas variables at 37°C or at patient (intravascular) temperature. In fact, all readings by the PT7 are made at patient (intravascular) temperature and then corrected, if required, to 37°C, as opposed to bench top analysers which measure at 37°C and correct to patient temperature. A subtle difference, but differences in the temperature correction algorithms may lead to discrepancies in displayed values.

With regard to the statistical evaluation of the data, there are three principal methods of describing relationships between continuous variables: (1) assessment of whether or not two variables are associated, that is if the values of one variable tend to be higher (or lower) for higher (or lower) values of the other variable, using the method known as correlation, presuming that at least one of the variables has a normal distribution in the study population; (2) assessment of whether the value of one variable to be predicted from any known value of the other variable, for which the technique of linear regression is used; and (3) assessment of the level of agreement between the values of the two variables by calculating the mean difference between readings (bias) and the degree of variability (precision).[6]

For the study in question it is perhaps useful to know that high (or low) values from one monitor are reflected by high (or low) values from the other. Calculation of correlation coefficients and *P* values indicates how likely it is that a high (or low) value from one monitor is reflected by a high (or low) value from the other. No information on the level of agreement between the actual values displayed can be derived from this type of analysis. The PT7 monitor is designed to measure intra-arterial blood-gas tensions, not predict the values displayed by another monitor, thus calculation of regression statistics does not provide useful information on the performance of the sensor. Thus, results from correlation statistics should be interpreted with caution in this type of study and the technique of linear regression analysis should not be used.

The conclusion that the level of agreement between HCO_3^- and base excess was relatively poor requires further comment. As part of an ongoing study in our department, 28 arterial blood samples were aspirated from patients in our intensive care unit and analysed simultaneously by a single operator using two bench top blood-gas analysers (ABL 300; Radiometer, Copenhagen, Denmark and NOVA Stat Profile Plus 9; NOVA Biomedical, Waltham, MA USA). For assessment of bicarbonate concentration and base excess, the bias between machines was -0.74 mmol litre^{-1} and -0.57 mmol litre^{-1}, respectively. The precision of these readings (1.96 SD) was 4.50 and 4.47 mmol litre^{-1}, respectively. These values are of a similar magnitude to those obtained when comparing the PT7 system with the blood-gas analyser available for the study in question.

Finally, presentation of the levels of bias and precision in the units of the variables can be misleading. For example, for the above analysis the levels of bias and precision appear almost equal. However, the normal range for bicarbonate is numerically considerably larger than base excess and if bias and precision are calculated in percentage terms a different appraisal of the level of agreement is evident. For the data on bicarbonate, bias and precision were -1.59% and 16.92%, respectively. For the data on base excess, bias and precision were -43.25% and 206.72%, respectively. Therefore, when this type of data are presented, and values for bias and precision presented in the units of measurement, percentage bias and precision should also be quoted to give a more comprehensive assessment of the level of agreement.

6. Altman DG. *Practical Statistics for Medical Research.* London: Chapman and Hall, 1991; 277–321.

Sir,—Thank you for the opportunity to respond to the comments of Dr Graystone and Dr Venkatesh on our article.[1] They highlighted some important technical aspects. During use of the intra-arterial sensor system, a correction of the Paratrend 7 (PT7) values on the basis of those obtained by *in vitro* blood-gas measurement is possible. This correction may be termed readjustment or recalibration, the difference being rather semantic. However, as described, no such correction was used in our study. This is important when rating the agreement of PT7 with laboratory *in vitro* blood-gas measurements, which is considered to be the gold standard,[2] and also when comparing results of our study with previous clinical work, where such corrections were used.[3–5]

Furthermore, we agree that the algorithms built into the PT7 monitor and the bench top blood-gas analysers are crucial for the accuracy of all calculated parameters. Both the correction for measured blood-gas values from (intravascular) patient temperature to 37°C (and vice versa) and calculation of bicarbonate and base excess rely on these algorithms. Therefore, a study on the accuracy of a new system, which provides these values, indirectly includes comparison of the algorithms incorporated in this new system with those of the *in vitro* blood-gas analyser. Interestingly, the accuracy of these calculated variables which are displayed on the PT7 monitor has not been clinically investigated previously. The conflict remains, that ". . . the clinical performance of an optode-based blood-gas monitor must be judged in comparison with the gold standard electrode-based blood gas analyzer, for which clinical performance cannot be specifically quantified".[2]

At the time of preparation of our manuscript the PT7 sensor had been validated by only one group of authors. Since then Abraham, Gallagher and Fink[5] have reported on its clinical evaluation in different intensive care units. They followed a study design different from ours with special emphasis on continuous monitoring during a prolonged period of time. However, the results of their study may have been influenced by the fact that eight different bench top analysers from two different manufacturers were used in three different institutions. Furthermore, we stated that the PT7 system had been validated for limited blood-gas ranges only. This is true, as the ranges reported by Venkatesh, Clutton-Brock and Hendry[4] do not include clinically critical values of hypoxaemia and hypercapnia. However, we had the opportunity to measure some extreme values of arterial $P\mathrm{o}_2$ (6.1 kPa) and $P\mathrm{co}_2$ (9.5 kPa) during thoracoscopic surgery.

Calculation of bias and precision is considered standard statistics for comparing this type of data.[6] In addition, linear regression analyses were performed to facilitate comparison with previous work.[7] It is important to note that both types of statistical analyses consistently revealed good agreement between PT7 derived and blood-gas analyser derived values for arterial $P\mathrm{o}_2$, $P\mathrm{co}_2$ and pH, and also consistently documented significant scattering between PT7 derived and blood-gas analyser derived values such as bicarbonate and base excess.[1]

Finally, although clinical outcome and cost effectiveness studies are lacking in many other monitoring tools currently used in anaesthesia and intensive care, we agree fully that evidence-based, outcome-related data are mandatory for general acceptance of continuous intra-arterial blood-gas monitoring.

The future of ethical treatment

Sir,—Drs Mohr and Kettler raised important issues in their article on the ethical aspects of resuscitation.[1] Previously published guidelines have stressed the importance of obtaining patient views in decisions on whether or not to resuscitate.[2] In one large study examining the views of the elderly on admission to hospital, 186 patients from a total of 400 were deemed mentally incompetent to complete a questionnaire satisfactorily.[3] In such cases more emphasis may be placed on the views of relatives, and with an ageing population this is likely to occur more frequently.

Experience in the USA has shown that the judicial review of continuation of "futile" end of life treatment often fails to resolve differences between medical attendants and the next-of-kin. Unfortunately, in many cases the catalyst to a decision is the health insurance provider who may cap the amount spent on such care.[4]

We must be careful that we share the load of the decision making process without overburdening patients, relatives or ourselves with what will undoubtedly be increasingly difficult ethical dilemmas as the population becomes relatively more aged.

P. J. Shirley
Department of Anaesthesia
Aberdeen Royal Infirmary
Aberdeen

3. Bruce-Jones P, Roberts H, Bowker L, Cooney V. Resuscitating the elderly: what do the patients want? *Journal of Medical Ethics* 1996; **22**: 154–159.
4. Cantor NL. Can healthcare providers obtain judicial intervention against surrogates who demand "medically inappropriate" life support for incompetent patients? *Critical Care Medicine* 1996; **24**: 883–887.

Sir,—Dr Shirley raises the issue of overburdening patients, relatives and health care providers with the decision making process in ethical conflicts. In general, physicians are obligated to help patients and their surrogates to make competent decisions. However, it is important to distinguish between true advice and the more paternalistic approach of leaving the decision to the doctor [1]

We agree that the expectations on the decision making capacity of patients and their relatives should not be over-estimated; it might be limited because of the emotional involvement and lack of medical knowledge and comprehension. In case of conflict, such as the surrogates' wishes to continue futile treatment, we have to accept the obligation and responsibility family members feel towards their relatives. However, refusal of futile treatment should not be judged as unjustified paternalism, as in some situations physicians or other health care providers have to solve dilemmas and make decisions which they cannot transfer to relatives. We feel that the concept of patient's (and surrogate's) autonomy should not be abandoned, but its value is not absolute.[3]

The question that must be answered is how to distinguish between justified and unjustified refusal of patients' or relatives' wishes.[3] The apparent dilemma might be solved by an approach summarized as clinical pragmatism: a method of assessing the relevant facts; diagnosing the moral problems; considering the options; and negotiating goals and offering an (ethical) acceptable treatment plan that coheres with agreed goals.[2] In several ethical dilemmas, a process of creative problem solving might be appropriate instead of asking the attorney to make the decisions for us.

BOOK REVIEWS

Practical Anaesthesia and Analgesia for Day Surgery. J. M. Millar, G. E. Rudkin and M. Hitchcock. Published by Bios, Oxford. Pp. 250; indexed; illustrated. Price £19.95.

The three main authors of this 250-page paperback are practising day surgery anaesthetists whose intent is to inform the reader about "Safe selection of patients, the best anaesthetic techniques and the most effective analgesia" for patients attending a day surgery unit. They undertake this exercise in a style reminiscent of Lee and Atkinson's *Synopsis of Anaesthesia*; short pithy chapters with brief paragraphs of text and frequent use of lists and tables. Friendly "information bytes" appear highlighted on almost every page and contain the authors' interpretation of the preceding text, for example "always consider more suitable alternatives before giving morphine to day cases".

The subject matter ranges from chapters on patient selection to cost effectiveness and covers all relevant aspects of day-case anaesthesia, including drugs, techniques, sedation, PONV and analgesia, paediatrics and discharge. There is a useful chapter on anaesthesia for eight different surgical sub-specialties, each section covering anaesthetic issues, strategies for managing patients and likely problems encountered.

This is not a definitive study of anaesthesia and analgesia for day surgery but it is a very well referenced and clearly presented synopsis of the subject. The authors succeed in their intention to inform the reader of the most appropriate techniques available and provide well précised evidence for their conclusions and advice. The book can be used as a practical guide for trainees embarking on day-case anaesthesia and for those wishing to study further any particular aspect of the topics covered; each chapter concludes with an up-to-date list of references which will provide a useful starting point for their research.

The book will also be a useful addition to the day unit library and will appeal to trainees preparing for examinations. Its style and clear presentation make the book appropriate for nursing staff and it would also provide a good description to management of the practical side of anaesthetists' duties in the day unit.

D. Raitt

MCQs and OSCEs for the Primary FRCA. E. Doyle and P. Goggin. Published by Butterworth Heinemann, Oxford. Pp 155; indexed; illustrated. Price £14.99.

New examinations elicit new books to help candidates, editors, authors and publishers. *MCQs and OSCEs for the Primary FRCA* has emerged ahead of the new Primary examination introduced by the Royal College of Anaesthetists, alongside the recent changes to postgraduate specialist medical training in the UK.

This book of questions states its objectives clearly in the introduction and achieves them well. It aims to cover a wide range of topics, give some information, prompt further reading and identify gaps in knowledge. The book is divided into five papers of 60 questions rather than 3.3 papers of 90 questions. Each paper contains questions from throughout the Primary syllabus. At the end of each paper are answers, many of which are qualified by short explanations and the occasional reference.

Before the MCQ papers there are two paragraphs of advice on how to sit an MCQ examination. They contain exactly the sensible suggestions that are forgotten so easily immediately the examination begins.

The MCQs are plentiful, but there are only seven OSCE questions. The OSCE questions have one group of related data or one illustration with a single question. Candidates will find that they will encounter a battery of structured questions relating to each station of clinical data, equipment, history taking or examination should they proceed beyond the MCQ paper in the Primary examination.

Yes this book will help candidates to prepare for the Primary FRCA multiple choice paper, *no* it has not filled the gap in the market for a book on the OSCEs, and *I do not know* if the £15.00 premium to the examination fee will make that fee more likely to be a "once only" payment.

D. J. R. Duthie

Methods in Molecular Biology, volume 83: Receptor Signal Transduction Protocols. R. A. J. Challis (editor). Published by Humana Press, New Jersey. Pp. 275; indexed; illustrated. Price £99.50.

This book is unlikely to be of interest to the majority of practising anaesthetists. However, for those actively engaged in laboratory research the protocols described might be useful and for some essential.

For example, the pathophysiology of sepsis and its interrelated cytokine networks is currently being dissected in many laboratories. With recent advances in technique, many of which are described in this book, we are now beginning to unravel events at the intracellular level. It may be that this different perspective will simplify a complex and often confusing field. The *Methods in Molecular Biology* series aims to present a collection of linked, easy to follow protocols that can be used at the bench. This particular volume (83) examines in some depth an array of methodologies that examine ligand–receptor and receptor–effector interactions, particularly as they relate to G protein coupled receptors. Many techniques are described, some of which will be familiar to scientists from other disciplines. They include protocols for the preparation of primary antibodies; immunohistochemistry; northern analysis; *in situ* hybridization; methods of altering specific residues in receptor subunits to examine the effect on ligand interaction; and ways of expressing different receptor subunits in various cell systems. More specific protocols that describe the preparation of membrane fragments and measurement of radioligand binding, functional assays of guanine nucleotide exchange at G proteins after agonist binding and techniques to identify and quantitate particular G proteins involved in signalling events are also included. The description of technique and methodology in the majority of cases is detailed and written clearly. Helpful notes are given at the end of each section; usually these are items that you need to know and learn only by experience.

Clearly this is not a book to be read from cover to cover. It is a manual of relevant techniques that will sit comfortably on the top shelf of a laboratory cupboard, in easy reach when inspiration and guidance are required.

J. Slavin

Essentials of Pediatric Intensive Care, 2nd Edn. D. L. Levin and F. C. Morriss (editors). Published by Churchill Livingstone, London. Pp. 1813; indexed; illustrated. Price £48.00.

Paediatric intensive care in the British Isles is undergoing considerable change: the National Health Service has developed a strategy for the future; the Intercollegiate Committee formed by the Royal Colleges of Anaesthesia, Paediatrics and Child Health, and Surgeons has been entrusted with the task of establishing, shaping and approving postgraduate training; specialist status is recognized by the General Medical Council; and trainees are setting their sights on a long-term career in the field. The timing is perfect for a good textbook on paediatric intensive care.

Over the past 10 yr several North American textbooks have defined the domain of expertise and the core knowledge required to practise paediatric intensive care effectively. However, such are the developments in the specialty and general hospital care that one can extrapolate a "critical care" aspect to almost any acute problem requiring admission to hospital. Consequently, rather than becoming more concise, textbooks on the subject have generally increased in size. *Essentials of Pediatric Intensive Care* is no exception. Nevertheless, Levin and Morriss have undertaken and achieved a phenomenal task.

Essentials of Pediatric Intensive Care has the reputation of being a very practical guide. The second edition will not disappoint the reader: 252 contributors with almost every aspect of clinical paediatric intensive care discussed. There is even a chapter written by parents giving their special perspective. The first volume is devoted to pathophysiology, monitoring and treatment, and the second to procedures, equipment and techniques. Nurse and medical practitioners will find that despite its size this is the type of textbook that is helpful and instructive at the bedside. Summary boxes, illustrations and algorithms serve as useful guides and quick references—sadly, the supplementary pocket guide with all of these incorporated, a feature of the first edition, is not supplied with the latest edition. For those such as myself with a predominantly metropolitan practice, the chapters on "shark attack" and "snake envenomations" are a fascinating read. My only criticism is that the reproduction of the radiology examples is generally poor and in some instances woefully inadequate. The only omissions that I could find were: (1) discussion of tracheal tube fixation methods commonly used in the UK and the rest of Europe; (2) a chapter on non-invasive mechanical ventilation; and (3) a chapter on how to set-up a teaching and training programme with suggested requirements for attaining specialist status.

My overall conclusion is that this new edition of *Essentials of Pediatric Intensive Care* remains a very practical textbook and has improved with the expansion to two volumes: a thumbs-up, must-buy, will-use type of book. I recommend it for personal use, but would also suggest that each paediatric intensive care unit has it as part of their library. The only disadvantage for me is that its size implies that I am unlikely to have it with me as a reference when I need it—surely publishers should be moving towards an electronic age with CD versions! Dare I ask, "Is there a web-site yet?"

R. C. Tasker

Manual of Acute Pain Management in Children. I. McKenzie, P. B. Gaukroger, P. Ragg and T. C. K. (Kester) Brown (editors). Published by Churchill Livingstone, Edinburgh. Pp. 224; indexed, illustrated. Price £25.00.

Anyone *au fait* with paediatric anaesthesia will instantly recognize most of the editors of this manual, although why (Kester) Brown has to be named specifically is a mystery. Surely it would be too much of a coincidence to have two paediatric anaesthetists with the initials "T. C. K.", both with the same surname? Nevertheless, this minor irritation does not detract from a worthwhile project.

This manual has 14 contributors from the principal paediatric Australian units, most of whom are anaesthetists with some input from paediatricians, neonatologists and a nurse. The foreword is written by Flank Shann, an intensivist, thus widening further the range of available expertise. However, the reader should not be discouraged by Dr Shann's assertion that this book has been written for "ward medical, surgical and paramedical staff" as there is much that even the most experienced of specialist anaesthetists will find of value. However, academic high-fliers should turn to some other source if they wish to be bogged down by the minutiae of the science of paediatric pain and its treatment, as this is very much a practical manual designed for those working at the coal face of paediatric pain.

The chapters predictably consist of the various techniques available for providing pain relief, for example minor analgesics, nitrous oxide, opioids, PCA, extradural analgesia and peripheral nerve blocks. There are techniques described for providing analgesia in specific situations, such as burns, oncology for neonates, ICU, accident and emergency, and rheumatology, all of which provide good practical advice. However, the strongest selling points are the many algorithms and protocols which are present in great detail throughout the different chapters and in a series of appendices. These are of value not only to physicians organizing a paediatric pain team from the start but also to those with established pain teams. Indeed there is much to interest your reviewer and his colleagues, despite any reputation, deserved or otherwise, which our unit may enjoy.

What are the criticisms? There are a few. The main one concerns the physical make up of the manual which, as an approximately A3 sized paperback, is not easily transported or sturdy, and is more suitable as a bench book rather than an easily accessible manual. The order of the chapters could be set out more logically. It would have been neater to have pain assessment and safety and monitoring before the techniques of pain relief rather than after. A chapter dedicated to pharmacology would have been useful as would highlighted learning points, a device used by many modern textbooks. It may be that the editors have tried to be too brief at the expense of some detail and a list of recommended further reading after each chapter would have been worthwhile.

This is a textbook which will undoubtedly adorn the library shelves of hospital libraries throughout the land. It is to be hoped that it will also be taken down, read, and some of the excellent advice throughout its pages used to provide a framework for setting up and providing pain relief for the children in our care.

L. R. (Roddie) McNicol

Anesthesia and Resuscitation. R. D. M. Jones and R. B. Holland (editors). Published by Butterworth–Heineman, Oxford. Indexed; illustrated.

This book is intended for newly qualified doctors, to "bridge the gap" between academic knowledge and clinical responsibility that all medical graduates must undertake on becoming a house officer. It consists of 38 chapters written by 16 contributors, the majority of whom practice in Australia.

The book is divided into four sections with the majority of chapters written in a short notes/bulleted list style to maintain brevity and clarity. The first section consists of 19 short chapters which cover basic principles of anaesthesia and include pre- and postoperative care, monitoring, general and regional anaesthesia. They are concise but well written and would be ideal introductory texts to new anaesthetists.

The next two sections are in a similar style and cover resuscitation and care of the critically ill patient. Again, they are succinct and easily readable. One chapter is dedicated to crisis management algorithms which have recently been published in anaesthesia journals.

The fourth section covers emergency care of recreational injuries, including hyper- and hypothermia, altitude sickness and decompression injuries. There is also an interesting chapter on management of envenomation by various species indigenous to Australia.

The appendices cover nearly 100 pages and have useful sections on "how to be a streetwise houseofficer", writing examination answers and a compendium of drugs, some of which are not applicable to UK practice. There is also a comprehensive operating theatre discussion guide for undergraduates which would be extremely useful for anaesthetists who teach students.

Personally I liked the style of this book, however I feel it is probably too advanced as "a houseman's guide," although this may reflect the differences in UK and Australian training. For a small textbook it covers a huge range of topics and would probably serve as a useful introductory text for someone considering a career in anaesthesia.

A. Ogilvy

Cardiac Anaesthesia: A Practical Handbook. N. C. Hwang and M. Sinclair. Published by Oxford University Press, Oxford. Pp. 160; indexed; illustrated. Price £45.00.

This handbook is divided into 23 chapters comprising three sections: anatomy, physiology and pharmacology; anaesthesia for adults; and anaesthesia for children. The opening chapters on anatomy, physiology and pharmacology are excellent and give a concise, but clear background to the subsequent clinical sections. Addressing "drugs used in cardiac anaesthesia", thumbnail sketches of anaesthetic, cardiovascular and anticoagulant drugs are outlined. Other drugs described under "organ protection" make up the mixers which complete the cocktail of drugs delivered in cardiac anaesthetic rooms and theatres.

The book is intended for anaesthetic trainees, occasional cardiac anaesthetists and nurses. The clinical sections give unambiguous, straightforward direction, which is frequently unsubstantiated. There is no attempt to be comprehensive in the brief format of the handbook. The techniques reflect UK practice and are appropriate and safe. Emphasis rests on the delivery of anaesthetic care rather than management of likely complications.

Prior knowledge of the text would allow the reader to understand the progress of a cardiac anaesthetic and provide a foundation on which to build clinical experience. The book would be ideal in content and length for a trainee to read before encountering an attachment to cardiac anaesthesia, then re-read at the end of a week to a fortnight in cardiac theatres.

There is some repetition of procedures common to both adults and children in the two clinical sections, which allows either paediatric or adult cardiac anaesthetic practice to be read first. The style of the handbook succeeds better if the sections are read as a narrative. There is not enough space for detail and too brief an index to use the book for reference.

Having read and enjoyed the book from cover to cover at a single sitting the only real disappointment is the ending. The fine introductory chapters lead well into adult cardiac practice. The special requirements of paediatric practice follow, and the book ends with "Early postoperative management". As the index comes into sight on the right hand page, the book ends with the paediatric patient lying in asystole with the chest open. Surely a brief paragraph about the possible improvements in outcome of patients with correctable congenital cardiac anomalies would have sustained better the appreciation of this well paced, enthusiastic and interesting handbook?

D. J. R. Duthie

Anaesthetic Physiology and Pharmacology. W. McCaughey, R. S. J. Clarke, J. P. H. Fee and W. F. M. Wallace (editors). Published by Churchill Livingstone, Edinburgh. Pp. 778; indexed; illustrated. Price £60.00.

This new textbook is a sequel to the well-known *Clinical Anaesthetic Pharmacology*, edited by the late John Dundee. It is a multi-authored text with all the contributors except six emanating from Northern Ireland; although the majority are anaesthetists, the list of contributors also includes distinguished physiologists and obstetricians, and a cell biologist, nephrologist, chemical pathologist and consultant haematologist. The editors' stated intention is to integrate physiology, pharmacology and anaesthesia and they have emphasized those aspects of particular relevance to anaesthesia or critical care.

The quality of the contributors ensures that this text is up to date, accurate and pertinent to clinical practice. However, even with tight editing, the real issue is whether or not it is feasible to cover all the physiological and pharmacological knowledge required of a trainee anaesthetist within a mere 778 pages. For example, chapter one of 10 pages describes chemistry related to anaesthetic practice, and although in a section on "properties on gases and vapours" describes very briefly Boyle's law, solubility, osmotic pressure and ionization, there is no mention of gas viscosity or density. Clinical studies and statistics are covered in a mere 14 pages, albeit well but it is doubtful if comprehension could be obtained from such a short description as opposed to revision of prior knowledge acquired by delving into larger and more discursive texts.

In a seven-page chapter on anaesthetic gases, the space available for describing the effects induced by the blood-gas solubility of nitrous oxide would be inadequate to satisfy the first part of the FRCA examination. Many similar examples could be chosen from throughout this text.

In summary, the editors have attempted the impossible in venturing to encompass within such a circumscribed space the huge knowledge base required in physiology and pharmacology for the anaesthetic trainee. The fact that the end product is so good is a testimony to the quality of the editing and ability of the contributors. I shall certainly use this book frequently in future and shall recommend it to trainees with a caveat that many sections will require supplementation by reading elsewhere in the quest for either comprehension or factual knowledge.

G. Smith

Rapid Sequence Review of Anaesthesiology with Time-limited Pressure. W. K. Chee. Published by Butterworth-Heinemann, Oxford. Pp. 168. Price £27.50.

Professor Chee has written this book for those North American trainees who feel "completely overwhelmed by the amount of information presented in major textbooks", or for those approaching "board examinations" without sufficient time to read larger texts. Although such candidates would be better advised to defer their examinations until more adequately prepared, Professor Chee has attempted to write for them a book whose contents are "concise yet comprehensive . . . and . . . highly concentrated". He also sets an example to us all, in this litigious world, by taking pains to "disclaim any liability caused by direct or indirect application of the information in this book"!

After sitting three international anaesthetic examinations I am in a good position to review this book. I will do so with regard to its usefulness to fellowship candidates who find themselves in either of the above categories. The book attempts to cover most aspects of anaesthesia using headings and lists which might provide frameworks for essays. Commencing with "ABC" and airway problems, then the challenges of pregnancy and paediatrics, chapters proceed to cover trauma, various medical pathologies, anaesthesia for vascular procedures, regional blocks, chronic pain, monitoring and equipment, and some basic pharmacology. Overt omissions include anatomy, ambulatory surgery, infectious diseases/immunosuppression and acute pain relief.

The weakness of a book which has only one contributing author is apparent in the variable standard of information between chapters. Topics which are better covered include obesity, neonatal anaesthesia, and some medical subjects, including cardiovascular and neuromuscular disease. The chapter on respiratory disease contained some useful information, although I was surprised to find that cystic fibrosis, bronchiectasis and bronchopleural fistula did not feature, given their propensity to feature in examinations. One of the hallmarks of the book is its clear, well laid out charts, comparing and contrasting various related pathologies, drugs or equipment. However, I did not like the way in which the resuscitation algorithm (which, incidentally, differed from current European guidelines) was presented as a chart; it should be regarded as a sequence of events, rather than a tick-box which gives lignocaine equal importance to adrenaline in the treatment of ventricular fibrillation.

Inadequate chapters include chapter 20 (pain), a subject of increasing prominence in examinations, which covers only "reflex sympathetic dystrophy" (no "complex regional pain syndromes" here!) and three blocks (stellate ganglion, lumbar sympathetic and coeliac plexus). Backache (the topic of one of my clinical examinations) and the neuralgias are not mentioned. Furthermore, the blocks in both this chapter and chapter19 (regional anaesthesia) are described with little information on techniques and appropriate drug solutions. "Ventilatory modes in ICU" (p. 147) omits BiPAP and HFPPV. "Useful for weaning an intubated patient from the ventilator" is not the first phrase that springs to mind when considering Ayre's T-piece (p. 148). Chapter 9 (trauma) ignores the sequence of primary and secondary surveys, and would have done better to expand on the subjects of facial and thoracic trauma than to merely list them as possible occurrences. Transfusion therapy is also poorly covered.

Obviously 168 pages cannot include everything, particularly when the text is so widely spaced, but this book fell short of the usefulness I found with my own favourite crammer-style textbooks in several respects. First, the amount of information in the book is well below the standard required of the final FRCA (although it may be of some value to part 1 candidates in the clinical part of their examination). Second, the author has not quite appreciated the type of information which fellowship candidates easily forget and upon which they may need prompting in the days immediately preceding the examinations. (Admittedly there is more than adequate room on each page to add one's own notes, but there are cheaper ways of making a notebook.) Third, with its A4 size pages and weighing 580 g, it is too cumbersome a book to be carried around easily and opened when convenient. Fourth, the lack of an index diminishes the user-friendliness of the book. Finally, Professor Chee has managed to neither provoke nor inspire readers to be familiar with the more important well known articles or current controversies (only four references and a bibliography are listed), and to be able to discuss how these relate to one's own practice. It is knowledge such as this which helps to signify to the examiner that one is ready to embark upon the next stage of training.

SUBJECT INDEX

1997 Yearbook of Intensive Care and Emergency Medicine, Vincent, J. L., (editor), (*R*) 693

Acid–base equilibrium, Drugs in modern resuscitation, Vincent, R. 188–197
Acid–base equilibrium, pH, Converting pH and H$^+$, Walling, P. T., (*C*) 262–263
——, Converting pH and H$^+$: a rule for the other thumb, Girling, D. K., (*C*) 410
——, Converting pH and H$^+$: a "rule of thumb", Burden, R. J., *et al.*, (*e*) 413
Advanced life support, Advanced life support guidelines, Robertson, C. E. 172–177
Age factors, Pharmacokinetic–pharmacodynamic modelling of the EEG effects of Ro 48-6791, a new short-acting benzodiazepine, in young and elderly subjects, Dingemanse, J., *et al.* 567–574
Airway, Management of the airway and ventilation during resuscitation, Gabbott, D. A., *et al.* 159–171
——, Management of the airway and ventilation during resuscitation, Richardson, C., (*C*) 814
Airway, complications, Aspects of resuscitation in trauma, Nolan, J. P., *et al.* 226–240
Allergy, Intradermal compared with prick testing in the diagnosis of anaesthetic allergy, Fisher, M. McD, *et al.* 59–63
Anaesthesia and Resuscitation, Jones, R. D. M., *et al.*, (editors), (*R*) 819
Anaesthesia, audit, Anaesthesia and the competence revolution, Greaves, J. D., (*E*) 555–557
——, Autotransfusion in major orthopaedic surgery: experience with 1785 patients, Borghi, B., *et al.* 662–664
——, *Meta-analysis*: greater than the sum of its parts? Souter, M. J., *et al.*, (*E*) 420–421
——, Preliminary survey into clinical attitudes to computer based decision support systems, Beatty, P. C. W., (*ARS*) 140–141P
——, Simulated anaesthetic emergencies, Byrne, A. J., *et al.*, (*C*) 690–691
——, Simulated anaesthetic emergencies, Gaba, D. M., *et al.*, (*C*) 689–690
——, Simulated anaesthetic emergencies, Kurrek, M., *et al.*, (*C*) 689
Anaesthesia, aviation, Catalogue of human error, Arnstein, F. 645–656
Anaesthesia, day-case, Comparison of perioperative ketoprofen 2.0 mg kg^{-1} with 0.5 mg kg^{-1} i.v. in small children during adenoidectomy, Nikanne, E., *et al.* 606–608
Anaesthesia, depth, Absence of memory for intraoperative information, Hooper, M. B., (*C*) 143
——, Absence of memory for intraoperative information, Wang, M., *et al.*, (*C*) 143
——, Comparison of two steady state-auditory-evoked response methods for assessing depth of anaesthesia in routine clinical practice, Swart, M. L., *et al.*, (*ARS*) 677–678P
——, Effect of extradural analgesia on the paradoxical arousal response of the electroencephalogram, Kiyama, S., *et al.* 750–753
——, Pharmacodynamics of thiopentone: nocifensive reflex threshold changes correlate with hippocampal electroencephalography, Archer, D. P., *et al.* 744–749
Anaesthesia, duration, Emergence times from xenon anaesthesia are independent of the duration of anaesthesia, Goto, T., *et al.* 595–599
Anaesthesia, general, Absence of memory for intraoperative information, Hooper, M. B., (*C*) 143
——, Absence of memory for intraoperative information, Wang, M., *et al.*, (*C*) 143
——, Anaesthesia for laparoscopic cholecystectomy in a patient with Eisenmenger's syndrome, Sammut, M. S., *et al.* 810–812
——, Comparison of extradural and general anaesthesia on the fibrinolytic response to total knee arthroplasty, Sharrock, N. E., *et al.* 29–34
——, Induction of anaesthesia with sufentanil is associated with blood volume redistribution, Spiegel, T.v., *et al.*, (*EACTA*) A.3
——, Time-frequency spectral analysis of heart rate variability during induction of general anaesthesia, Huang, H.-H., *et al.* 754–758
Anaesthesia, human error, Catalogue of human error, Arnstein, F. 645–656
Anaesthesia, journals, Personal reflections, Smith, G., (*E*) 1–2
Anaesthesia, obstetric, Comparison of single, end-holed and multi-orifice extradural catheters when used for continuous infusion of local anaesthetic during labour, Dickson, M. A. S., *et al.* 297–300
——, Effects of volume on spinal anaesthesia with 0.25% hyperbaric bupivacaine, King, H.-K., (*C*) 262
——, Extradural buprenorphine suppresses breast feeding after Caesarean section, Hirose, M., *et al.* 120–121
——, Outcome of labour using low-dose extradural bupivacaine compared with intramuscular pethidine, Robinson, P N., *et al.*, (*ARS*) 675–676P
——, Ropivacaine 0.75% for extradural anaesthesia in elective Caesarean section: an open clinical and pharmacokinetic study in mother and neonate, Morton, C. P. J., *et al.* 3–8
Anaesthesia, paediatric, Cardiovascular effects and time-course of action of cisatracurium in infants and children during thiopentone–alfentanil–nitrous oxide–oxygen anaesthesia, Meretoja, O. A., *et al.*, (*ARS*) 683–684P
——, Comparison of propofol and isoflurane ameliorating effects during rewarming period in paediatric cardiac surgery, Çamcý, E., *et al.*, (*EACTA*) A.58
——, Comparison of suxamethonium and different combinations of rocuronium and mivacurium for rapid tracheal intubation in children, Naguib, M., *et al* 450–455
——, Laryngeal mask airway and uncuffed trachael tubes are equally effective for low flow or closed system anaesthesia in children, Frohlich, D., *et al.* 289–292
——, Metabolic, biochemical and haemodynamic effects of infusion of propofol for long-term sedation of children undergoing intensive care, Martin, P. H., *et al.* 276–279
——, Obstruction of the lumen of a plastic 15-mm connector inserted into a cut paediatric tube—Is it possible to avoid this damage? Preis, C. A., *et al.*, (*C*) 692
——, Propofol in paediatric intensive care, Hatch, D. J., (*E*) 274–275
——, Rebound pulmonary vasoconstriction and desaturation on withdrawal of nitric oxide in infants after cardiac surgery, Knapik, P., *et al.*, (*EACTA*) A.94
——, Serum concentrations of bupivacaine during prolonged continuous paravertebral infusion in young infants, Cheung, S. L. W., *et al.* 9–13
——, Sevoflurane or halothane for paediatric endoscopy, Plowman, A., *et al.*, (*C*) 143–144
Anaesthetic Physiology and Pharmacology, McCaughey, W., *et al.*, (editors), (*R*) 820

Anaesthetic techniques, closed-system, Quantitative study of Lowe's square-root-of-time method of closed-system anaesthesia, Couto da Silva, J. M., *et al.* 103–112

Anaesthetic techniques, extradural, A survey of the practice of thoracic epidural analgesia in the United Kingdom, Romer, H. C., *et al.*, (*EACTA*) A.89

——, Comparison of extradural and general anaesthesia on the fibrinolytic response to total knee arthroplasty, Sharrock, N. E., *et al.* 29–34

——, Effect of extradural analgesia on the paradoxical arousal response of the electroencephalogram, Kiyama, S., *et al.* 750–753

——, Extradural catheter-related infections in patients with infected cutaneous wounds, Bengtsson, M., *et al.* 668–670

——, Outcome of labour using low-dose extradural bupivacaine compared with intramuscular pethidine, Robinson, P. N., *et al.*, (*ARS*) 675–676P

——, Ropivacaine 0.75% for extradural anaesthesia in elective Caesarean section: an open clinical and pharmacokinetic study in mother and neonate, Morton, C. P. J., *et al.* 3–8

——, Ropivacaine test dose in extradural anaesthesia, Dresner, M., *et al.*, (*C*) 813

——, Ropivacaine test dose in extradural anaesthesia, Morton, C. P. J., *et al.*, (*C*) 813

Anaesthetic techniques, extubation, Intravenous clonidine administration during CPB: effects on haemodynamic parameters and extubation time, Abay, G., *et al.*, (*EACTA*) A.8

Anaesthetic techniques, hypotensive, Platelet function is inhibited by nitric oxide liberation during nitroglycerin-induced hypotension anaesthesia, Aoki, H., *et al.* 476–481

Anaesthetic techniques, induction, A physiological model of induction of anaesthesia with propofol in sheep. 1. Structure and estimation of variables, Upton, R. N., *et al.* 497–504

——, A physiological model of induction of anaesthesia with propofol in sheep. 2. Model analysis and implications for dose requirements, Ludbrook, G. L., *et al.* 505–513

——, Comparison between halothane and sevoflurane for adult vital capacity induction, Hall, J. E., *et al.* 285–288

Anaesthetic techniques, laryngoscopy, Accurate measurement of "true glottic view", Groom, P , *et al.*, (*ARS*) 680–681P

——, Epiglottis modelling in a computer simulation of difficult laryngoscopy, Hawkins, M., *et al.*, (*ARS*) 136–137P

——, Modelling the photographic "restricted window" to derive "true glottic view", Groom, P., *et al.*, (*ARS*) 136P

——, Skin vasomotor reflex induced by laryngoscopy: comparison of the McCoy and Macintosh blades, Shimoda, O., *et al.* 714–718

Anaesthetic techniques, low flow, Quantitative study of Lowe's square-root-of-time method of closed-system anaesthesia, Couto da Silva, J. M., *et al.* 103–112

Anaesthetic techniques, regional, Does the addition of clonidine affect duration of analgesia of bupivacaine wound infiltration in inguinal hernia surgery? Elliott, S , *et al.* 446–449

——, Interactions between mivacurium and prilocaine, Torrance, J. McK., *et al.*, (*C*) 262

——, Interactions between mivacurium and prilocaine, Wildsmith, J A. W., (*C*) 262

——, I.v. regional anaesthesia. Comparison of 0 25% prilocaine with or without 5% dextrose, Makin, A., *et al.*, (*ARS*) 687P

Anaesthetic techniques, regional, extradural, The use of thoracic epidural analgesia after lung transplantation, Westerlind, A., *et al.*, (*EACTA*) A.82

Anaesthetic techniques, regional, paravertebral, Serum concentrations of bupivacaine during prolonged continuous paravertebral infusion in young infants, Cheung, S. L. W., *et al.* 9–13

Anaesthetic techniques, subarachnoid, Effects of volume on spinal anaesthesia with 0.25% hyperbaric bupivacaine, King, H.-K., (*C*) 262

——, Knee–chest *vs* horizontal side position during induction of spinal anaesthesia in patients undergoing lumbar disc surgery, Laakso, E., *et al.* 609–611

——, Spinal anaesthesia: effect of the site of injection on the spread of analgesia, Kamenik, M., (*C*) 144

——, Spinal anaesthesia: effect of the site of injection on the spread of analgesia, Veering, B. Th., *et al.*, (*C*) 144–145

——, Transient neurological symptoms after spinal anaesthesia with 4% mepivacaine and 0.5% bupivacaine, Hiller, A., *et al.* 301–305

——, Transient radicular irritation after spinal anaesthesia with 2% isobaric lignocaine, Ramasamy, D., *et al.* 394–395

Anaesthetics gases, nitric oxide, Inhaled nitric oxide during anaesthesia for lung transplant, Della Rocca, G., *et al.*, (*EACTA*) A.77

Anaesthetics gases, nitrous oxide, Differential effects of nitrous oxide and propofol on myogenic transcranial motor evoked responses during sufentanil anaesthesia, Ubags, L. H., *et al.* 590–594

——, Dissociation between the effect of nitrous oxide on spontaneous and reflexly evoked sympathetic activity in dogs, Ma, D., *et al.* 525–529

——, Does nitrous oxide antagonize sevoflurane-induced hypnosis? Katoh, T., *et al.* 465–468

——, Effect of 100% oxygen and 50% nitrous oxide on cerebral autoregulation as assessed by the transient hyperaemic response test, Girling, K. J., *et al.*, (*ARS*) 131P

——, Emergence times from xenon anaesthesia are independent of the duration of anaesthesia, Goto, T , *et al* 595–599

Liver, Hepatic venous blood flow measured with retrograde thermodilution technique, Christiansen, C. L., *et al.*, (*EACTA*) A.55

Liver, blood flow, Desflurane *vs* isoflurane in liver transplantation: a comparison of outcomes, O'Beirne, H. A., *et al.*, (*ARS*) 132P

Liver, cirrhosis, Pharmacokinetics of controlled release morphine (MST) in patients with liver cirrhosis, Kotb, H. I. M., *et al.* 804–806

Liver, transplantation, Changes in inflammatory mediators during orthotopic liver transplantation, Bellamy, M. C., *et al.* 338–341

——, Desflurane *vs* isoflurane in liver transplantation: a comparison of outcomes, O'Beirne, H. A., *et al.*, (*ARS*) 132P

——, Functional iron deficiency in orthotopic liver transplantation, Davey-Quinn, A., *et al.*, (*ARS*) 684–685P

Lung, Efficacy of a vital capacity manœuvre to prevent post-cardiopulmonary bypass atelectasis. An experimental study, Magnusson, L., *et al.*, (*EACTA*) A.57

Lung, adult respiratory distress syndrome, Oxygenation criteria—a plea for more information, Nielsen, M. S., *et al.*, (*C*) 260

——, Oxygenation criteria—a plea for more information, Peek, G. J., *et al.*, (*C*) 260

Lung, blood flow, Quantitative assessment of inhomogeneity of myocardial blood flow by a single breath inert gas technique. A model study, Kazmaier, S., *et al.*, (*EACTA*) A.33

——, Reperfusion after supracoeliac aortic cross-clamping in a rat model: effects of fluid-loading on mesenteric oxygen transport, lactate flux and jejunal luminal PCO_2, Wu, X., *et al.*, (*EACTA*) A.48

Lung, emphysema, Perioperagive medical care of patients undergoing bilateral lung volume reduction for severe emphysema, Vassalli, F., *et al.*, (*EACTA*) A.79

——, Perioperative management for lung volume reduction surgery for severe emphysema, Gressier, M., *et al.*, (*EACTA*) A.78

Lung, function, Comparison of the effects of isoflurane with those of propofol on pulmonary vascular impedance in experimental embolic pulmonary hypertension, Ewalenko, P., *et al.* 625–630

——, Effects of ventilation during cardiopulmonary bypass on pulmonary shunt, compliance and structure, Erhan, E., *et al.*, (*EACTA*) A.56

——, Inhaled nitric oxide in acute respiratory failure, Young, J. D., (*E*) 695–696

——, Postoperative respiratory dysfunction: is the site of surgery crucial? McKeague, H., *et al.*, (*E*) 415–416

——, Postoperative spirometry after laparoscopy for lower abdominal or upper abdominal surgical procedures, Joris, J., *et al.* 422–426

Lung, mucus, Comparison of isoflurane with propofol on respiratory cilia, Raphael, J. H., *et al.* 473–475

Lung, respiratory failure, Anaesthesia for the surgery of emphysema, Conacher, I. D. 530–538

Lung, trachea, Comparison of isoflurane with propofol on respiratory cilia, Raphael, J. H., *et al* 473–475

Lung, transplantation, Anaesthesia for the surgery of emphysema, Conacher, I. D. 530–538

Lung, vascular resistance, Impact of preoperative pulmonary vascular resistance and ischaemic time on the cardiovascular function after orthotopic heart transplantation, Bertolissi, M., *et al.*, (*EACTA*) A.61

Lung, volume, Anaesthesia for the surgery of emphysema, Conacher, I. D 530–538

Lung, water, Change in extravascular lung water after re-expansion of the collapsed lung in sheep measured by the thermo-saline dilution method, Nakatsuka, M., *et al.*, (*EACTA*) A.76

——, Total blood volume, central blood volume, and extravascular lung water in children and adults, Wietasch, G., *et al.*, (*EACTA*) A.59

Malignant hyperthermia, Detection of a novel mutation at amino acid position 614 in the ryanodine receptor in malignant hyperthermia, Quane, K A., *et al.* 332–337

——, Dystrophin deficient *mdx* muscle is not prone to MH susceptibility: an *in vitro* study, Mader, N., *et al.* 125–127

——, Genetic analysis reveals single recombinants in malignant hyperthermia, Curran, J. L , *et al.*, (*ARS*) 134P

——, Histological support for the difference between malignant hyperthermia susceptible (MHS), equivocal (MHE) and negative (MHN) muscle biopsies, Mezin, P., *et al.* 327–331

Manual of Acute Pain Management in Children, McKenzie, I , *et al.*, (editors), (*R*) 819

Manual of Drug Interactions for Anesthesiology, 3rd Edn, Mueller, R. A., *et al.*, (*R*) 265

MCQs and OSCEs for the Primary FRCA, Doyle, E , *et al.*, (*R*) 818

Measurement techniques, An analysis of myocardial ischaemia and serial cardiac troponin I measurements in patients undergoing CABG surgery, Tupper-Carey, D. A., *et al.*, (*EACTA*) A.29

——, Awake or asleep pulmonary artery catheter insertion? A comparison of catecholamine and haemodynamic responses, O'Connor, P. J., *et al.*, (*EACTA*) A.31

——, Cerebral haemodynamic effects of intra-aortic balloon counterpulsation, Weyland, A., *et al.*, (*EACTA*) A.53

——, Hepatic venous blood flow measured with retrograde thermodilution technique, Christiansen, C. L., *et al.*, (*EACTA*) A.55

——, Induction of anaesthesia with sufentanil is associated with blood volume redistribution, Spiegel, T.v., *et al.*, (*EACTA*) A.3

——, Postoperative myocardial ischaemia and changes in indices of myocardial oxygen balance in patients undergoing CABG surgery, Tupper-Carey, D. A., *et al.*, (*EACTA*) A.36

——, Pulse contour cardiac output measurement corresponds better with standard dilution technique than continuous thermodilution technique after hypothermic bypass, Bottiger, R. H., *et al.*, (*EACTA*) A.32

——, Quality control of carotid artery thrombendarterectomy by intraoperative transit time flow and resistance measurements, Walpoth, B. H., *et al.*, (*EACTA*) A.37

——, Quantitative assessment of inhomogeneity of myocardial blood flow by a single breath inert gas technique. A model study, Kazmaier, S., *et al.*, (*EACTA*) A.33

Measurement techniques, calorimetry, Comparison between reverse Fick and indirect calorimeter measurements of oxygen consumption in patients with fulminant hepatic failure, Walsh, T. S., *et al.*, (*ARS*) 131–132P

Measurement techniques, cardiac output, Comparison of the accuracy of the lithium dilution technique with the thermodilution technique for measurement of cardiac output, Kurita, T., *et al.* 770–775

——, Overestimation of low cardiac output measured by thermodilution, Tournadre, J. P., *et al.* 514–516

Measurement techniques, Doppler ultrasonography, Effect of incremental doses of sevoflurane on cerebral pressure autoregulation in humans, Gupta, S., *et al.* 469–472

Measurement techniques, electroencephalography, Does the insertion of earplugs affect the bispectral index of the sedated patient in the intensive care unit? Pearson, A. J., *et al.*, (*ARS*) 685–686P

Measurement techniques, Fick principle, Comparison between reverse Fick and indirect calorimeter measurements of oxygen consumption in patients with fulminant hepatic failure, Walsh, T. S., *et al.*, (*ARS*) 131–132P

Measurement techniques, flowmetry, Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles, Abdulatif, M., *et al.* 24–28

——, Comparison of the accuracy of the lithium dilution technique with the thermodilution technique for measurement of cardiac output, Kurita, T., *et al.* 770–775

——, Gut mucosal perfusion in infants undergoing cardiopulmonary bypass: effect of preoperative captopril, Booker, P. D., *et al.* 14–18

——, Overestimation of low cardiac output measured by thermodilution, Tournadre, J. P., *et al.* 514–516

——, Skin vasomotor reflex induced by laryngoscopy: comparison of the McCoy and Macintosh blades, Shimoda, O., *et al.* 714–718

Measurement techniques, gas exchange, Accuracy and clinical performance of a continuous intra-arterial blood-gas monitoring system during thoracoscopic surgery, Zollinger, A., *et al.* 47–52

——, Continuous intra-arterial blood-gas monitoring, Graystone, S. J., (*C*) 815–816

——, Continuous intra-arterial blood-gas monitoring, Venkatesh, B , (*C*) 815

——, Continuous intra-arterial blood-gas monitoring, Zollinger, A., *et al.*, (*C*) 816–817

Measurement techniques, histology, Histological support for the difference between malignant hyperthermia susceptible (MHS), equivocal (MHE) and negative (MHN) muscle biopsies, Mezin, P., *et al.* 327–331

Measurement techniques, indication dilution, Acute effect of mitral valve replacement on extravascular lung water in patients receiving colloid or crystalloid priming of cardiopulmonary bypass, Buhre, W., *et al.* 311–316

Measurement techniques, lithium dilution, Comparison of the accuracy of the lithium dilution technique with the thermodilution technique for measurement of cardiac output, Kurita, T., *et al.* 770–775

Measurement techniques, magnetic resonance imaging, Magnetic resonance imaging of the extradural space of the thoracic spine, Hirabayashi, Y., *et al.* 563–566

Measurement techniques, magnetic resonance spectroscopy, Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part I: elimination from the head, Lockwood, G. G., *et al.* 581–585

——, Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part II: functional localization, Lockwood, G. G., *et al.* 586–589

Measurement techniques, microalbuminuria, Use of microalbuminuria as an indicator for the development of sepsis and multiple system organ failure, MacKinnon, K. L., *et al.*, (*ARS*) 678P

Measurement techniques, near-infrared spectroscopy, Near-infrared spectroscopy for testing cerebral CO_2 reactivity, Kraus, B., *et al.*, (*EACTA*) A.34

Measurement techniques, neural network, artificial, Artificial neural networks for distinguishing disturbed from undisturbed breathing, Caleb, P., *et al.*, (*ARS*) 682P

Measurement techniques, neuromuscular block, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al.*, (*ARS*) 683P

Measurement techniques, spectral analysis, Time-frequency spectral analysis of heart rate variability during induction of general anaesthesia, Huang, H.-H., *et al.* 754–758

Measurement techniques, spectrophotometry, Detection of arrhythmogenic cellular magnesium depletion in hip surgery patients, Zuccala, G., *et al.* 776–781

Measurement techniques, thermodilution, Comparison of the accuracy of the lithium dilution technique with the thermodilution technique for measurement of cardiac output, Kurita, T., *et al.* 770–775

——, Overestimation of low cardiac output measured by thermodilution, Tournadre, J. P., *et al.* 514–516

Measurement techniques, tonometry, Gut mucosal perfusion in infants undergoing cardiopulmonary bypass: effect of preoperative captopril, Booker, P. D., *et al.* 14–18

Measurement techniques, transoesophageal Doppler, Overestimation of low cardiac output measured by thermodilution, Tournadre, J. P., *et al.* 514–516

Measurement techniques, transoesophageal echocardiography, Comparison of propofol-fentanyl and isoflurane-fentanyl anaesthesia with transoesophageal echocardiography for coronary artery bypass graft surgery, Nicolaides, A., *et al.*, (*EACTA*) A.45

——, Doppler monitoring of diastolic left ventricular function does not increase the sensitivity of dobutamine stress echocardiography for detecting inducible demand ischaemia in anaesthetized patients, Seeberger, M. D., *et al.*, (*EACTA*) A.40

——, Echocardiographic and haemodynamic differences among patients undergoing the MAZE procedure, Bakola, A. A., *et al.*, (*EACTA*) A.44

——, Improved intraoperative assessment of aortic stentless valves using transoeosophageal echocardiography, Morris, M. J., (*EACTA*) A.43

——, Normal values for intraoperative left ventricular systolic and diastolic function as assessed by transoesophageal echocardiography, Skarvan, K., *et al.*, (*EACTA*) A.39

——, Perioperative transoesophageal echocardiography with low dose dobutamine: A feasible test for viability? Palmgren, I., *et al.*, (*EACTA*) A.41

——, Transoesophageal echocardiography in cardiac and vascular surgery: therapeutic implications and inter-observer differences, Schmidlin, D., *et al.*, (*EACTA*) A.38

——, Transoesophageal echocardiography in the I.C.U. setting: luxury or necessity? Lagonidis, D., *et al.*, (*EACTA*) A.46

——, Transoesophageal echocardiography of mitral and pulmonary venous flow as estimation of diastolic function, Pittarello, D., *et al.*, (*EACTA*) A.42

——, Transoesophageal echocardiography of the right ventricle in thoracic patients, McMahon, C. C., *et al.*, (*EACTA*) A.75

Measurement techniques, ultrasound, Ultrasonographic measurement of gastric emptying in volunteers: assessment of technique and effect of low-dose dopamine, Goldhill, D. R., *et al.*, (*ARS*) 136P

Measurement techniques, voltammetry, Actions of tramadol, its enantiomers and principal metabolite, O-desmethyltramadol, on serotonin (5-HT) efflux and uptake in the rat dorsal raphe nucleus, Bamigbade, T. A., *et al* 352–356

Medico-legal, consent, Ethical aspects of resuscitation, Mohr, M., *et al.* 253–259

——, The future of ethical treatment, Mohr, M., *et al.*, (*C*) 817

——, The future of ethical treatment, Shirley, P. J., (*C*) 817

Memory, Absence of memory for intraoperative information, Hooper, M. B., (*C*) 143

——, Absence of memory for intraoperative information, Wang, M., *et al.*, (*C*) 143

Metabolism, Changes in human coronary sinus blood flow and myocardial metabolism induced by ventricular fibrillation and defibrillation, Runsio, M., *et al.*, (*EACTA*) A.20

——, Comparison of midazolam and propofol effects on cerebral metabolism during cardiopulmonary bypass, Suzer, A., *et al.*, (*EACTA*) A.52

——, Effect of intravascular volume load after induction of anaesthesia on oxygen consumption in cardiac surgery patients, Ballesteros, M., *et al.*, (*EACTA*) A.19

——, Influence of sevoflurane on cerebral metabolism, blood flow and CO_2-reactivity, Mielck, F., *et al.*, (*EACTA*) A 6

——, Myocardial circulatory and metabolic effects of clevidipine after coronary artery bypass grafting (CABG), Kieler-Jensen, N., *et al.*, (*EACTA*) A.12

——, Significance of regional cerebral oxygen saturation (rSO_2) during open heart surgery, Papadimitriou, L., *et al.*, (*EACTA*) A.51

——, The effects of sevoflurane on regional myocardial blood flow and metabolism, when used to control intraoperative hypertension in patients undergoing coronary artery bypass grafting, Kirnö, K., *et al.*, (*EACTA*) A.5

Methods in Molecular Biology, volume 83: Receptor Signal Transduction Protocols, Challis, R. A. J., (editor), (*R*) 818

Model, burn injury, Effect of systemic N-methyl-D-aspartate receptor antagonist (dextromethorphan) on primary and secondary hyperalgesia in humans, Ilkjær, S., *et al.* 600–605

Model, computer simulation, Epiglottis modelling in a computer simulation of difficult laryngoscopy, Hawkins, M., *et al.*, (*ARS*) 136–137P

——, Simulated anaesthetic emergencies, Byrne, A J., *et al.*, (*C*) 690–691

——, Simulated anaesthetic emergencies, Gaba, D. M., *et al.*, (*C*) 689–690

——, Simulated anaesthetic emergencies, Kurrek, M., *et al.*, (*C*) 689

——, The expanding role of simulators in risk management, Byrne, A. J., *et al.*, (*C*) 411

Model, mathematical, Effect of haemoglobin concentration on brain oxygenation in focal stoke: a mathematical modelling study, Dexter, F., *et al.* 346–351

Model, mouse, Dystrophin deficient *mdx* muscle is not prone to MH susceptibility: an *in vitro* study, Mader, N., *et al.* 125–127

Model, neuroblastoma cells, Effect of halothane on K^+ and carbachol stimulated noradrenaline release and increased , in SH-SY5Y human neuroblastoma cells, Atcheson, R., *et al.* 78–83

Model, pharmacokinetic, Plasma dilution and the rate of infusion of Ringer's solution, Hahn, R G., *et al.* 64–67

Model, physiological, A physiological model of induction of anaesthesia with propofol in sheep. 1. Structure and estimation of variables, Upton, R. N., *et al.* 497–504

——, A physiological model of induction of anaesthesia with propofol in sheep. 2. Model analysis and implications for dose requirements, Ludbrook, G. L., *et al.* 505–513

——, Repeated enflurane anaesthetics and model predictions: a study of the variability in the predictive performance measures, Vermeulen, P. M., *et al.* 488–496

Model, pig, Efficacy of a vital capacity manœuvre to prevent post-cardiopulmonary bypass atelectasis: An experimental study, Magnusson, L., *et al.*, (*EACTA*) A.57

——, Pigs are not human, Lentschener, C., *et al.*, (*C*) 691–692

——, Pigs are not humans, Bazin, J. E., *et al.*, (*C*) 691

Model, rabbit, Halothane reduces reperfusion injury after regional ischaemia in the rabbit heart *in vivo*, Schlack, W , *et al.* 88–96

Model, rat, Actions of tramadol, its enantiomers and principal metabolite, O-desmethyltramadol, on serotonin (5-HT) efflux and uptake in the rat dorsal raphe nucleus, Bamigbade, T. A., *et al.* 352–356

——, Comparison of midazolam and thiopental on arrhythmias in ischaemia and reperfusion conditions in isolated perfused rat hearts, Suzer, Ö., *et al.*, (*EACTA*) A.1
——, Halothane decreases K^+ evoked glutamate release from rat cerebrocortical slices, Nicol, B., *et al.*, (*ARS*) 140P
——, No direct effects of dopexamine on the isolated perfused rat kidney, Leuwer, M., *et al.*, (*ARS*) 132P
——, Opioid systems and the newborn, Marsh, D. F., *et al.* 787–795
——, Reperfusion after supracoeliac aortic cross-clamping in a rat model: Effects of dopexamine on mesenteric oxygen transport, lactate flux and jejunal luminal PCO_2, Wu, X., *et al.*, (*EACTA*) A.49
——, Reperfusion after supracoeliac aortic cross-clamping in a rat model: effects of fluid-loading on mesenteric oxygen transport, lactate flux and jejunal luminal PCO_2, Wu, X., *et al.*, (*EACTA*) A.48
——, Studies on the binding of amethocaine to rat cerebrocortical membranes, Kudo, T., *et al.* 521–524
Model, sheep, Change in extravascular lung water after re-expansion of the collapsed lung in sheep measured by the thermo-saline dilution method, Nakatsuka, M., *et al.*, (*EACTA*) A.76
——, Imipramine poisoning in an animal model-treatment with single cardiopulmonary bypass support or additional reinhaemoperfusion? Schmidt, W., *et al.*, (*EACTA*) A.64
Model, simulation, Accurate measurement of "true glottic view", Groom, P., *et al.*, (*ARS*) 680–681P
——, Modelling the photographic "restricted window" to derive "true glottic view", Groom, P., *et al.*, (*ARS*) 136P
Monitoring, Awake or asleep pulmonary artery catheter insertion? A comparison of catecholamine and haemodynamic responses, O'Connor, P. J., *et al.*, (*EACTA*) A.31
——, Echocardiographic and haemodynamic differences among patients undergoing the MAZE procedure, Bakola, A. A., *et al.*, (*EACTA*) A.44
——, Quality control of carotid artery thrombendarterectomy by intraoperative transit time flow and resistance measurements, Walpoth, B. H., *et al.*, (*EACTA*) A.37
Monitoring, blood gases, Continuous intra-arterial blood-gas monitoring in infants and children with cyanotic heart disease, Hatherill, M., *et al.* 665–667
——, Cutaneous blood gas monitoring during rigid bronchoscopy with high frequency Jet ventilation (HFJV), Ausseur, A., *et al.*, (*EACTA*) A.74
Monitoring, cardiac output, Estimation of cardiac output using the Maxima breathing system, Miller, D. M., *et al.*, (*ARS*) 682–683P
Monitoring, colour kinesis, Validity of acoustic quantification colour kinesis for detection of left ventricular regional wall motion abnormalites: a transoesophageal echocardiographic study, Hartmann, T., *et al.* 482–487
Monitoring, echocardiography, Validity of acoustic quantification colour kinesis for detection of left ventricular regional wall motion abnormalites: a transoesophageal echocardiographic study, Hartmann, T., *et al.* 482–487
Monitoring, electrocardiography, Cardioventilatory coupling during anaesthesia, Galletly, D. C., *et al.* 35–40
Monitoring, electroencephalography, Effect of extradural analgesia on the paradoxical arousal response of the electroencephalogram, Kiyama, S., *et al.* 750–753
——, Pharmacodynamics of thiopentone: nocifensive reflex threshold changes correlate with hippocampal electroencephalography, Archer, D. P., *et al.* 744–749
——, Pharmacokinetic–pharmacodynamic modelling of the EEG effects of Ro 48-6791, a new short-acting benzodiazepine, in young and elderly subjects, Dingemanse, J., *et al.* 567–574
Monitoring, evoked potentials, Bolus doses of alfentanil prevent the increase in Pa amplitude associated with intubation in a dose-dependent manner, Shinner, G., *et al.*, (*ARS*) 137–138P
——, Differential effects of nitrous oxide and propofol on myogenic transcranial motor evoked responses during sufentanil anaesthesia, Ubags, L. H., *et al.* 590–594
——, Midlatency auditory evoked potentials and motor signs of wakefulness during anaesthesia with midazolam, Schwender, D., *et al.* 53–58
Monitoring, neuromuscular function, Assessment of neuromuscular monitoring by intensive care nurses: comparison of the TOF-watch and tactile assessment, Greer, R., *et al.*, (*ARS*) 138–139P
Monitoring, temperature, Heat retention using passive systems during anaesthesia: comparison of two plastic wraps, one with reflective properties, Deacock, S., *et al.* 766–769
Monitoring, transoesophageal echocardiography, Assessment of a new ventricular contractile index obtained with transoesophageal echocardiography before and after cardiopulmonary bypass in cardiac surgical patients, Kikura, M., *et al.* 759–765
Monitoring, ventilation, Cardioventilatory coupling during anaesthesia, Galletly, D. C., *et al.* 35–40
Muscle skeletal, Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles, Abdulatif, M., *et al.* 24–28
Muscle skeletal, blood flow, Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles, Abdulatif, M., *et al.* 24–28
Muscle skeletal, diaphragm, Effects of temperature on phrenic nerve and diaphragmatic function during cardiac surgery, Mills, G. H., *et al.* 726–732
Muscle vascular, responses, Role of endothelium in the modulation of isoflurane-induced vasodilatation in rat thoracic aorta, Kirstetter, P., *et al.* 84–87
Muscles, skinned fibres, Is there a difference in myofilament calcium sensitivity between malignant hyperthermia susceptible and normal skeletal muscle? Enright, S. M., *et al.*, (*ARS*) 685P

Neonates, Opioid systems and the newborn, Marsh, D. F., *et al* 787–795
Nerve, damage (postoperative), Prognosis of intraoperative brachial plexus injury: a review of 22 cases, Ben-David, B., *et al.* 440–445
Nerve, neurotransmitters, Effects of ketamine and pentobarbitone on acetylcholine release from the rat frontal cortex *in vivo*, Kikuchi, T., *et al.* 128–130
——, Enhanced choline acetyltransferase activity does not explain the action of inhaled convulsants, Griffiths, R., *et al.* 389–391
Nerve, somatic, Dissociation between the effect of nitrous oxide on spontaneous and reflexly evoked sympathetic activity in dogs, Ma, D., *et al.* 525–529
Neuromuscular block, atracurium, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al.*, (*ARS*) 683P
Neuromuscular block, cisatracurium, Cardiovascular effects and time-course of action of cisatracurium in infants and children during thiopentone–alfentanil–nitrous oxide–oxygen anaesthesia, Meretoja, O. A., *et al.*, (*ARS*) 683–684P
——, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al.*, (*ARS*) 683P
Neuromuscular block, measurement of response, Administration of magnesium sulphate before rocuronium: effects on speed of onset and duration of neuromuscular block, Kussman, B., *et al.* 122–124
——, Assessment of neuromuscular monitoring by intensive care nurses: comparison of the TOF-watch and tactile assessment, Greer, R., *et al.*, (*ARS*) 138–139P
——, Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles, Abdulatif, M., *et al.* 24–28
——, Interactions between mivacurium and pancuronium, Kim, K. S., *et al.* 19–23
——, Twitch augmentation and train-of-four fade during onset of neuromuscular block after subclinical doses of suxamethonium, Kim, S. Y., *et al.* 379–381
Neuromuscular block, mivacurium, Blood flow and mivacurium-induced neuromuscular block at the orbicularis oculi and adductor pollicis muscles, Abdulatif, M., *et al.* 24–28
——, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al.*, (*ARS*) 683P
——, Comparison of suxamethonium and different combinations of rocuronium and mivacurium for rapid tracheal intubation in children, Naguib, M., *et al.* 450–455
——, Interactions between mivacurium and pancuronium, Kim, K. S., *et al* 19–23
——, Interactions between mivacurium and prilocaine, Torrance, J. McK., *et al.*, (*C*) 262
——, Interactions between mivacurium and prilocaine, Wildsmith, J. A. W., (*C*) 262
Neuromuscular block, pancuronium, Interactions between mivacurium and pancuronium, Kim, K. S., *et al.* 19–23
Neuromuscular block, rocuronium, Administration of magnesium sulphate before rocuronium: effects on speed of onset and duration of neuromuscular block, Kussman, B., *et al.* 122–124
——, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al.*, (*ARS*) 683P
——, Comparison of rocuronium and suxamethonium for use

during rapid sequence induction of anaesthesia, McCourt, K C, *et al.*, (*ARS*) 134P
——, Comparison of suxamethonium and different combinations of rocuronium and mivacurium for rapid tracheal intubation in children, Naguib, M., *et al* 450–455
——, Spontaneous movements associated with rocuronium: is pain on injection the cause? Borgeat, A., *et al.* 382–383
Neuromuscular block, suxamethonium, Comparison of rocuronium and suxamethonium for use during rapid sequence induction of anaesthesia, McCourt, K C., *et al.*, (*ARS*) 134P
——, Comparison of suxamethonium and different combinations of rocuronium and mivacurium for rapid tracheal intubation in children, Naguib, M., *et al* 450–455
——, Intraocular pressure and suxamethonium, Edmondson, L., (*C*) 146
——, Twitch augmentation and train-of-four fade during onset of neuromuscular block after subclinical doses of suxamethonium, Kim, S. Y., *et al.* 379–381
Neuromuscular block, vecuronium, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al*, (*ARS*) 683P
——, Effect of neuromuscular block using vecuronium on oxygen consumption in critically ill adults, Loan, P. B., *et al.*, (*ARS*) 684P
——, Rapid tracheal intubation with propofol, alfentanil and a standard dose of vecuronium, Groener, R., *et al.* 384–385
Neuromuscular relaxants, cisatracurium, Cisatracurium vs pancuronium for neuromuscular blockade in patients undergoing coronary revascularisation, Rauch, H., *et al.*, (*EACTA*) A.2
Neuromuscular relaxants, pancuronium, Cisatracurium vs pancuronium for neuromuscular blockade in patients undergoing coronary revascularisation, Rauch, H, *et al.*, (*EACTA*) A.2
Non-steroidal anti-inflammatory drugs, Pain after laparoscopy, Alexander, J I 369–378

Operating rooms, contamination, Environmental monitoring during gaseous induction with sevoflurane, Hall, J E, *et al.* 342–345
Oxygen, brain, Significance of regional cerebral oxygen saturation (rSO_2) during open heart surgery, Papadimitriou, L., *et al*, (*EACTA*) A.51
Oxygen, consumption, Comparison between reverse Fick and indirect calorimeter measurements of oxygen consumption in patients with fulminant hepatic failure, Walsh, T. S., *et al.*, (*ARS*) 131–132P
——, Effect of intravascular volume load after induction of anaesthesia on oxygen consumption in cardiac surgery patients, Ballesteros, M., *et al.*, (*EACTA*) A.19
——, Effect of neuromuscular block using vecuronium on oxygen consumption in critically ill adults, Loan, P. B., *et al.*, (*ARS*) 684P
——, Relationship between aortic cross clamp time and myocardial oxygen consumption during coronary artery bypass surgery (CABG), Langenberg, C. J M, *et al.*, (*EACTA*) A.50
Oxygen, delivery, Effect of neuromuscular block using vecuronium on oxygen consumption in critically ill adults, Loan, P. B., *et al.*, (*ARS*) 684P
Oxygen, gradients, Effect of assuming a fixed ($Ca_{O_2} - C\bar{v}_{O_2}$) on shunt calculations, Nirmalan, M., *et al.*, (*ARS*) 135P
Oxygen, saturation, Influence of pulse oximeter lower alarm limit on the incidence of hypoxaemia in the recovery room, Rheineck-Leyssius, A. T., *et al.* 460–464
Oxygen, therapy, Lanz tube as alternative for ICU hyperbaric oxygen therapy, Molnar, Z., *et al*, (*ARS*) 679–680P

Pain, chronic, Local anaesthetic agents inhibit $[^3H]$noradrenaline uptake into SH-SY5Y human neuroblastoma cells, Joyce, P. I., *et al*, (*ARS*) 677P
Pain, injection, Spontaneous movements associated with rocuronium: is pain on injection the cause? Borgeat, A., *et al.* 382–383
Pain Management for the Practising Physician, Irving, G. A, *et al*, (*R*) 265–266
Pain, measurement, Pre-emptive analgesia using local anaesthesia: a study in bilaterally symmetrical surgery, Campbell, W I., *et al.* 657–659
Pain, mechanism, Effect of systemic N-methyl-D-aspartate receptor antagonist (dextromethorphan) on primary and secondary hyperalgesia in humans, Ilkjær, S., *et al* 600–605
Pain, postoperative, Buscopan does not improve pain after laparoscopic sterilization, Wilson, C M., *et al.*, (*ARS*) 139–140P
——, Caudal tramadol for postoperative analgesia in paediatric hypospadias surgery, Prosser, D. P, *et al* 293–296
——, Does the addition of clonidine affect duration of analgesia of bupivacaine wound infiltration in inguinal hernia surgery? Elliott, S., *et al* 446–449

Pharmacodynamics, A physiological model of induction of anaesthesia with propofol in sheep. 1 Structure and estimation of variables, Upton, R. N., *et al.* 497–504
——, A physiological model of induction of anaesthesia with propofol in sheep. 2. Model analysis and implications for dose requirements, Ludbrook, G. L, *et al.* 505–513
——, Comparison of neuromuscular blocking effects and train-of-four fade of cisatracurium with other blocking agents, Carroll, M. T., *et al.*, (*ARS*) 683P
——, Computer-controlled infusion of ORG 21465, a water soluble steroid i v. anaesthetic agent, into human volunteers, Sneyd, J. R., *et al.* 433–439
Pharmacodynamics, Ro 48-6791, Pharmacokinetic–pharmacodynamic modelling of the EEG effects of Ro 48-6791, a new short-acting benzodiazepine, in young and elderly subjects, Dingemanse, J., *et al.* 567–574
Pharmacodynamics, thiopentone, Pharmacodynamics of thiopentone: nocifensive reflex threshold changes correlate with hippocampal electroencephalography, Archer, D. P, *et al.* 744–749
Pharmacokinetics, bupivacaine, Pharmacokinetic and clinical study of ropivacaine and bupivacaine in women receiving extradural analgesia in labour, McCrae, A. F, *et al.* 558–562
Pharmacokinetics, fentanyl, I.v. fentanyl decreases the clearance of midazolam, Hase, I., *et al.* 740–743
Pharmacokinetics, isoflurane, Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part I· elimination from the head, Lockwood, G. G, *et al* 581–585
——, Magnetic resonance spectroscopy of isoflurane kinetics in humans. Part II functional localization, Lockwood, G. G., *et al* 586–589
Pharmacokinetics, midazolam, I.v. fentanyl decreases the clearance of midazolam, Hase, I., *et al.* 740–743
——, Pharmacokinetics of midazolam given as an intranasal spray to adult surgical patients, Bjorkman, S, *et al* 575–580
Pharmacokinetics, models, Repeated enflurane anaesthetics and model predictions: a study of the variability in the predictive performance measures, Vermeulen, P. M., *et al.* 488–496
Pharmacokinetics, morphine, Pharmacokinetics of controlled release morphine (MST) in patients with liver cirrhosis, Kotb, H. I. M., *et al.* 804–806
Pharmacokinetics, ORG 21465, Administration to humans of ORG 21465, a water soluble steroid i.v anaesthetic agent, Sneyd, J. R., *et al.* 427–432
Pharmacokinetics, propofol, A physiological model of induction of anaesthesia with propofol in sheep 1 Structure and estimation of variables, Upton, R. N., *et al* 497–504
——, A physiological model of induction of anaesthesia with propofol in sheep. 2 Model analysis and implications for dose requirements, Ludbrook, G. L., *et al* 505–513
Pharmacokinetics, remifentanil, Effect of temperature and cardiopulmonary bypass on the pharmacokinetics of remifentanil, Russell, D., *et al.* 456–459
Pharmacokinetics, Ro 48-6791, Pharmacokinetic–pharmacodynamic modelling of the EEG effects of Ro 48-6791, a new short-acting benzodiazepine, in young and elderly subjects, Dingemanse, J., *et al.* 567–574
Pharmacokinetics, ropivacaine, Pharmacokinetic and clinical study of ropivacaine and bupivacaine in women receiving extradural analgesia in labour, McCrae, A. F., *et al.* 558–562
——, Ropivacaine 0.75 % for extradural anaesthesia in elective

Caesarean section. an open clinical and pharmacokinetic study in mother and neonate, Morton, C. P. J., *et al.* 3–8

——, Ropivacaine test dose in extradural anaesthesia, Dresner, M., *et al.*, (*C*) 813

——, Ropivacaine test dose in extradural anaesthesia, Morton, C. P. J., *et al.*, (*C*) 813

Pharmacology, buscopan, Buscopan does not improve pain after laparoscopic sterilization, Wilson, C. M., *et al.*, (*ARS*) 139–140P

Pharmacology, captopril, Gut mucosal perfusion in infants undergoing cardiopulmonary bypass: effect of preoperative captopril, Booker, P. D., *et al.* 14–18

Pharmacology, dextromethorphan, Effect of systemic N-methyl-D-aspartate receptor antagonist (dextromethorphan) on primary and secondary hyperalgesia in humans, Ilkjær, S., *et al.* 600–605

Pharmacology, domperidone, Effect of domperidone on the ventilatory response to transient hyperoxia in patients anaesthetized with isoflurane, Foo, I. T., *et al.* 41–46

Pharmacology, dopamine, Low-dose dopamine: there is a scientific rationale, Gelman, S., (*C*) 546

——, "Renal" dopamine, Girbes, A. R. J., *et al.*, (*C*) 263–264

——, "Renal" dopamine, Inglis, A., *et al.*, (*C*) 263

Pharmacology, "ecstacy", "Ecstacy" and the anaesthetist, Hall, A. P., (*E*) 697–698

Pharmacology, granisetron, Granisetron reduces the incidence of nausea and vomiting after middle ear surgery, Fujii, Y., *et al.* 539–540

Pharmacology, magnesium sulphate, Administration of magnesium sulphate before rocuronium: effects on speed of onset and duration of neuromuscular block, Kussman, B., *et al.* 122–124

——, Effects of magnesium sulphate on the cardiovascular system, coronary circulation and myocardial metabolism in anaesthetized dogs, Nakaigawa, Y., *et al.* 363–368

Pharmacology, *N*-acetylcysteine, *N*-acetylcysteine in multisystem organ failure, Molnar, Z., *et al.*, (*ARS*) 678P

Pharmacology, naloxone, Naloxone inhibits gastric emptying but not gastrointestinal transit in the rat, Asai, T., *et al.*, (*ARS*) 133P

Pharmacology, nicorandil, Beneficial effect of concomitant administration of isoflurane and nicorandil, Piriou, V., *et al.* 68–77

Pharmacology, niroglycerin, Platelet function is inhibited by nitric oxide liberation during nitroglycerin-induced hypotension anaesthesia, Aoki, H., *et al.* 476–481

Pharmacology, nitric oxide, Extra-pulmonary effects of inhaled nitric oxide in swine with and without phenylephrine, Troncy, E., *et al.* 631–640
